# COLLABORATORS ON THE DESIGN AND SHOP PRACTICE VOLUME OF THE ELEVENTH EDITION

**D. M. Avey**, Executive Secretary, American Foundrymen's Association, Chicago.—Formerly Editor of *The Foundry*. *Foundry Practice.*

**W. H. Bassett** (Deceased), Late Technical Superintendent, American Brass Co., Waterbury, Conn.—*Copper; Wrought Brasses, Bronzes and Nickel-silver Alloys.*

**Christopher H. Bierbaum**, Vice-President and Consulting Engineer, Lumen Bearing Co., Buffalo, N. Y.—*Bearing Metals.*

**Earle Buckingham**, Professor of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Mass.—*Gearing.*

**F. E. Cardullo**, Chief Engineer, G. A. Gray Co., Cincinnati, Ohio.—*Planers.*

**R. M. Cherry**, General Electric Co., Industrial Dept., Industrial Heating Section, Schenectady, N. Y.—*Industrial Electric Heating.*

**Eugene C. Clarke**, President, Chambersburg Engineering Co., Chambersburg, Pa.—*Forging Practice.*

**W. M. Corse**, Metallurgical and Chemical Engineer, Washington, D. C.—*Brass and Bronze; Sand-cast, Copper-base Alloys.*

**Theodore Crane**, Professor of Architectural Engineering, School of Fine Arts, Yale University, New Haven, Conn.—*Building Construction.*

**Robert C. Deale**, Tool Supervisor, E. W. Bliss Co., Brooklyn, N. Y.—*Single-point Metal Cutting Tools.*

**Jasper O. Draffin**, Professor of Theoretical and Applied Mechanics, Materials Testing Laboratory, University of Illinois, Urbana, Ill.—*Strength of Materials.*

**Hans Ernst**, Research Director, Cincinnati Milling Machine Co., Cincinnati, Ohio.—*Milling Machine Practice.*

**J. C. Fox**, Chief Chemist and Metallurgist, Doehler Die Castings Co., Toledo, Ohio.—*Die-casting Alloys.*

**John A. Gann**, Chief Metallurgist, Dow Chemical Co., Midland, Mich.—*Magnesium and Its Alloys.*

**J. C. Geniesse**, Research Chemist, Atlantic Refining Co., Philadelphia.—*Lubricants.*

**M. N. Halberg**, Industrial Dept., Motor Division, General Electric Co., Schenectady, N. Y.—*Electric Motors and Their Control.*

**Frederic V. Hetzel**, Consulting Engineer, West Chester, Pa.—Formerly Chief Engineer, Link Belt Co., Philadelphia, Pa.—*Materials Handling.*

**W. R. Hibbard**, Assistant Metallurgist, American Brass Co., Waterbury, Conn.—*Wrought Brass and Bronze.*

**R. E. Hiller**, Research and Development Engineer, Babcock & Wilcox Co., Barberton, Ohio.—*Welding.*

**J. C. Hodge**, Chief Metallurgist, Babcock & Wilcox Co., Barberton, Ohio.—*Welding.*

**H. A. S. Howarth**, Vice-President, Kingsbury Machine Works, Philadelphia, Pa.—*Oil Film Bearings.*

**H. G. Jennison**, Metallurgist, American Brass Co., Waterbury, Conn.—*Wrought Brass and Bronze.*

**Zay Jeffries**, Metallurgical Engineer, Nela Park, Cleveland, Ohio.—*Aluminum and Its Alloys; Tungsten and Molybdenum.*

**Edward R. Kent**, Architectural Engineer, Ridgewood, N. J.—*Strength of Materials.*

**Robert T. Kent**, Consulting Engineer, Verona, N. J.—*Properties of Materials; Specifications of Iron and Steel Products; Corrosion-resistant Alloys; Non-metallic Materials; Fabricated Materials; Fastenings; Rotating Members; Keys, Cotters, Fits, Pins, Tapers; Brakes; Structural Materials; Abrasive Processes; Measurements; Mechanical Power Transmission; Mechanism and Mechanics; Roller Bearings; Drills and Drilling; Metal Sawing; Machine Tool Drives, Feeds and Speeds.*

# COLLABORATORS ON THE DESIGN AND SHOP PRACTICE VOLUME

**R. L. Kenyon,** Research Metallurgist, American Rolling Mill Co., Middletown, Ohio.—*Armco Ingot Iron.*

**M. S. Kice, Jr.,** Chief Engineer, American Blower Co., Detroit, Mich.—*Dust Collection.*

**Arthur L. Kimball,** General Electric Co., Engineering General Dept., General Electric Co., Schenectady, N. Y.—*Vibration and Noise.*

**Matthew Luckiesh,** Research Director, General Electric Co., Nela Park, Cleveland, Ohio.—*Illumination.*

**Mario Martellotti,** Engineer, Research Dept., Cincinnati Milling Machine Co., Cincinnati, Ohio.—*Milling Machine Practice.*

**J. Spotts McDowell,** Research Engineer, Harbison-Walker Refractories Co., Pittsburgh, Pa.—*Refractories.*

**Paul D. Merica,** Director of Research, International Nickel Co., New York.—*General Properties of Metals and Alloys.*

**H. B. Morse,** Engineering Consultant, Toledo Machine and Tool Division, E. W. Bliss Co., Toledo, Ohio.—*Pressure Working of Metals.*

**N. K. B. Patch,** Chief Engineer, Lumen Bearing Co., Buffalo, N. Y.—*Non-ferrous Foundry Practice.*

**W. M. Peirce,** Research Division, New Jersey Zinc Co., Palmerton, Pa.—*Zinc and Its Alloys.*

**Thomas D. Perry,** Engineer in Woodworking, The Resinous Products and Chemical Co., Philadelphia.—*Woodworking.*

**Norman B. Pilling,** Manager, Research Laboratory, International Nickel Co., Bayonne, N. J.—*General Properties of Metals and Alloys.*

**Mortimer F. Sayre,** Professor of Applied Mechanics, Union College, Schenectady, N. Y.—*Springs.*

**Frank N. Speller,** Director, Dept. of Metallurgy and Research, National Tube Co., Pittsburgh, Pa.—*Corrosion of Metals.*

**Bradley Stoughton,** Dean of Engineering, Head of Dept. of Metallurgy, Lehigh University, South Bethlehem, Pa.—*Iron and Steel.*

**J. S. Tawresey,** Assistant Chief Engineer, S. K. F. Industries, Philadelphia, Pa.—*Ball Bearings.*

**Enrique Touceda,** Consulting Engineer, Albany, N. Y.—*Malleable Castings.*

**W. Trinks,** Professor of Mechanical Engineering, Carnegie Institute of Technology, Pittsburgh, Pa.—*Industrial Furnaces; Governing, Regulation and Control.*

**Sidney J. Williams,** Director, Public Safety Division, National Safety Council, Chicago, Ill.—*Safety Engineering.*

**Robert Worthington,** 20 Exchange Place, New York.—*Nickel and Its Non-ferrous Alloys.*

# PUBLISHER'S PREFACE

In making plans for new editions of our handbooks in mechanical engineering and in electrical engineering, it soon became clear that engineering science and practice had developed to such an extent that handbooks were growing beyond all practical bounds. They had become both bulky and inconvenient and contained much duplicated material. In order to solve the problems presented by these conditions, the editors of our various handbooks were asked to serve as an advisory editorial board.

This board recommended, first, that the fundamental material underlying all engineering be published in a separate volume, and, second, that the existing handbooks as they are revised be issued in several volumes containing material closely related to the specialized branches of engineering. As a result of these recommendations, the Wiley Engineering Handbook Series has been initiated, which in the beginning will comprise the following: Eshbach's "Handbook of Engineering Fundamentals"; Kent's "Mechanical Engineers' Handbook" in two volumes, viz., "Power" and "Design and Shop Practice"; Pender's "Electrical Engineers' Handbook" in two volumes, viz., "Electric Power" and "Communication and Electronics."

This division has also made it possible to devote more space to the various topics so that the entire new series of handbooks contains more complete information on all topics than heretofore has been possible. It is our hope that this new plan will give engineers information that is more useful, more complete, and in more convenient form.

John Wiley & Sons, Inc.

# PREFACE TO THE ELEVENTH EDITION

## March 1938.

The division of this handbook into two volumes has permitted a more thorough treatment of the material in the earlier editions and the inclusion of many new subjects. The development in the past ten years of many new materials of engineering and the improvement in tools, machinery and processes have made many of the data in the earlier editions obsolete. The book, therefore, has practically been rewritten. In the selection of material, the same principle has been applied that has governed the ten preceding editions, namely, that the book should cover the practice of mechanical engineering. The editor, and his collaborators, have presented the data that have been useful to them in their work as practicing engineers.

In order to make this volume complete in itself. some duplication of material in the other volumes of this series was necessary; for example, the mathematical tables and some of the data on the materials of engineering. This duplication has been kept to a minimum, and in all cases the material has been revised to accord more closely with the needs of the mechanical engineer.

The authorship of all special articles has been indicated in the text. Where no author appears, the material was prepared by the editor-in-chief. Every effort has been made to show all sources of material, and to give credit where credit is due.

The publishers and the editor-in-chief extend their thanks to all who have assisted in the preparation of this work, to the collaborators, to the many industrial organizations, and to the individuals who have offered valuable criticism and suggestions.

Robert Thurston Kent.

# ABSTRACT FROM PREFACE TO THE FIRST EDITION, 1895.

More than twenty years ago the author began to follow the advice given by Nystrom: "Every engineer should make his own pocket-book, as he proceeds in study and practice, to suit his particular business." The manuscript pocket-book thus begun, however, soon gave place to more modern means for disposing of the accumulation of engineering facts and figures, viz., the index rerum, the scrap-book, the collection of indexed envelopes, portfolios and boxes, the card catalogue, etc. Four years ago, at the request of the publishers, the labor was begun of selecting from this accumulated mass such matter as pertained to mechanical engineering, and of condensing, digesting, and arranging it in form for publication. In addition to this, a careful examination was made of the transactions of engineering societies, and of the most important recent works on mechanical engineering in order to fill gaps that might be left in the original collection, and insure that no important facts had been overlooked.

Some ideas have been kept in mind during the preparation of the Pocket-book that will, it is believed, cause it to differ from other works of its class. In the first place it was considered that the field of mechanical engineering was so great, and the literature of the subject so vast, that as little space as possible should be given to subjects which especially belong to civil engineering.

Another idea prominently kept in view by the author has been that he would not assume the position of an "authority" in giving rules and formulæ for designing, but only that of compiler, giving not only the name of the originator of the rule, where it was known, but also the volume and page from which it was taken, so that its derivation may be traced when desired. When different formulæ for the same problem have been found they have been given in contrast, and in many cases examples have been calculated by each to show the difference between them. In some cases these differences are quite remarkable. Occasionally the study of these differences has led to the author's devising a new formula, in which case the derivation of the formula is given.

Much attention has been paid to the abstracting of data of experiments from recent periodical literature, and numerous references to other data are given. In this respect the present work will be found to differ from other Pocket-books.

William Kent.

# TABLE OF CONTENTS

Alphabetical index follows Section 28

## SECTION 1—GENERAL PROPERTIES OF MATERIALS

PAGE
The Chemical Elements and Compounds .... 1–03
Properties of Materials .... 1–03
PAGE
Specific Gravity .... 1–10
Hardness .... 1–13
Compressibility .... 1–15

## SECTION 2—IRON AND STEEL

### Iron and Steel

Pig Iron .... 2–03
Cast Iron .... 2–03
Wrought Iron .... 2–04
Electrolytic and Ingot Iron .... 2–06
Steel .... 2–10
Metallography of Iron and Steel .... 2–12
Hardening, Annealing and Tempering .... 2–13
Alloy Steels .... 2–16
Standard Specifications for Steel Products .... 2–21
Automotive Steels .... 2–37

### Welding of Iron and Steel

Types of Welds .... 2–48
Physical Properties of Fusion Welds in Steel .... 2–52
Welding Design .... 2–53
Welding of Various Materials .... 2–58
Surfacing by Welding .... 2–60
Qualifications of Welders .... 2–60

## SECTION 3—CORROSION AND CORROSION-RESISTANT METALS

### Corrosion of Metals

Corrosion in General .... 3–03
Mechanism of Corrosion .... 3–03
Principles of Testing .... 3–06
Prevention of Corrosion .... 3–11
Paints and Varnishes .... 3–12
Protection Against Underwater Corrosion .... 3–16
Protection Against Soil Corrosion .... 3–18

### Corrosion-resistant Metals

Stainless Steel .... 3–19
High-silicon Alloys .... 3–24
Non-ferrous Alloys .... 3–25

## SECTION 4—NON-FERROUS METALS AND ALLOYS

General Properties of Metals and Alloys .... 4–03
Copper .... 4–09

### Zinc and Its Alloys

Properties of Zinc .... 4–10
Slab Zinc .... 4–12
Rolled Zinc .... 4–13

### Brass and Bronze

Sand-cast Copper-base Alloys .... 4–18
Wrought Brasses, Bronzes and Nickel-silver Alloys .... 4–23

### Aluminum and Its Alloys

Properties of Aluminum .... 4–25
Cast Aluminum Alloys .... 4–35
Wrought Aluminum Alloys .... 4–38
Heat Treatment of Aluminum Alloys .... 4–42
Fabrication of Aluminum .... 4–43
Joining of Aluminum .... 4–44
Finishing of Aluminum .... 4–45
Fabricated Aluminum Products .... 4–47
Electrical Uses of Aluminum .... 4–48
Structural Uses of Aluminum .... 4–49

### Nickel and Its Non-Ferrous Alloys

Properties of Nickel .... 4–49
Alloys of Nickel and Copper .... 4–51
Alloys of Copper, Nickel and Zinc .... 4–53
Alloys of Nickel and Chromium. Resistance Alloys .... 4–54

### Magnesium and Its Alloys

Properties of Magnesium .... 4–55
Magnesium Alloys .... 4–55
Fabrication and Use of Magnesium Alloys .... 4–58

### Tungsten and Molybdenum

Tungsten .... 4–58
Molybdenum .... 4–60

### Die-Casting Alloys

Tin-base Alloys .... 4–60
Lead- and Zinc-base Alloys .... 4–61
Copper-base Alloys .... 4–62

### Bearing Metals

Babbitt Metals .... 4–62
Bronze Alloys .... 4–64

### Solders

Lead-tin Solders .... 4–67
Silver Solders .... 4–67

# TABLE OF CONTENTS

## SECTION 5—NON-METALLIC MATERIALS

### Refractories

PAGE

Firebrick 5–03
Properties of Refractories 5–08
Mortars for Laying Refractory Brick 5–10
Commercial Firebrick 5–11
Miscellaneous Refractories 5–12
Applications of Refractories 5–17

### Wood

Properties of Wood 5–20

### Cork

Properties of Cork 5–25

### Rubber

Asbestos 5–37
Cement 5–38
Zirconia 5–38

## SECTION 6—FABRICATED MATERIALS

### Plates, Sheets, Bars, Rods and Shapes

Plates 6–03
Sheets 6–07
Bars and Rods 6–10
Shapes 6–12

### Steel, Copper and Other Wires

Plow Steel Wire 6–16
Cast Steel Wire 6–16
Wire for Telegraph and Telephone Lines 6–16
Non-ferrous Wires 6–19
Wire Gages and Sheet Metal Gages 6–23

### Ropes, Chains and Wire Rope

Ropes 6–26
Chains 6–30
Wire Rope 6–34

### Rivets, Nails and Washers

Rivets 6–47
Washers 6–50
Nails 6–51

## SECTION 7—STRENGTH OF MATERIALS

### Simple Stresses

Definitions 7–03
Work and Resilience 7–07
Combined Elementary Stresses 7–08
Allowable Stress and Factor of Safety 7–10
Repeated Stress 7–11
Energy or Dynamic Loads 7–15

### Beams

Theory of Flexure 7–17
Beams of Uniform Cross-section 7–25
Beams of Uniform Strength 7–27
Curved Beams 7–27
Continuous Beams 7–30
Axially End-loaded Beams 7–32

### Columns

Definitions 7–34
Column Formulas 7–35
Wooden Columns 7–37
Eccentric and Transverse Loads on Compression Members 7–38
Cast-iron Columns 7–40

### Shafts

Definitions 7–40
Determination of Torsional Stresses 7–41

### Cylinders, Plates and Rollers

Cylinders 7–44
Plates 7–47
Stresses in Solids under Pressure 7–49

### Testing of Materials

Equipment 7–51
Standard Test Pieces 7–53
Precautions Required in Making Tests 7–54
Interpretation of Test Results 7–55
Miscellaneous Tests 7–57

## SECTION 8—MECHANISM AND MECHANICS

### Elements of Machines

Elementary Machines 8–03
Applications of the Lever 8–06
Applications of the Inclined Plane 8–09
The Gyroscope 8–15

### Mechanics

Center of Gravity 8–16
Moment of Inertia 8–17
Center and Radius of Gyration 8–18
Velocity and Acceleration 8–18
Force, Work and Energy 8–19
Oscillation and Percussion 8–22

### Friction

Laws of Friction 8–23
Coefficients of Friction 8–24
Friction of Machine Elements 8–29

# TABLE OF CONTENTS

## SECTION 9—FASTENINGS

PAGE

### Screws and Screw Fastenings

Forms of Threads ........ 9–03
Screw Thread Standards ........ 9–04
Bolts, Nuts and Screws ........ 9–24
Strength of Fastenings ........ 9–43

### Rivets and Riveted Fastenings

Rivets ........ 9–47
Riveted Joints ........ 9–49

PAGE

Strength and Efficiency of Riveted Joints ........ 9–50

### Fastenings for Timber Joints

Methods of Failure ........ 9–54
Methods of Fastening Wood Joints ........ 9–54

## SECTION 10—MECHANICAL SPRINGS

Types of Springs ........ 10–03
Helical Compression and Extension Springs ........ 10–06
Torsion Springs ........ 10–14
Elliptical and Semi-elliptical Springs ........ 10–17
Flat Springs ........ 10–19
Vibration in Springs ........ 10–20
Endurance of Springs ........ 10–20
Comparative Efficiency of Springs ........ 10–21

## SECTION 11—ROTATING MEMBERS

### Axles and Shafts

Axles ........ 11–03
Shafts ........ 11–04
Critical Speed of Shafts ........ 11–10

### Cranks and Crank-pins

Proportions of Cranks ........ 11–10
Forces Acting on Cranks ........ 11–12

### Fly-wheels

Energy of Fly-wheels ........ 11–15
Weight of Fly-wheels ........ 11–17
Safe Speed of Fly-wheels ........ 11–19
Dimensions and Construction of Fly-wheels ........ 11–21

## SECTION 12—KEYS, COTTERS, PINS, TAPERS AND FITS

Keys ........ 12–03
Cottered Joints ........ 12–13
Pins ........ 12–14
Tapers ........ 12–17
Fits ........ 12–23

## SECTION 13—BEARINGS AND LUBRICANTS

### Oil Film Bearings with Perfect Lubrication

Journal Bearings ........ 13–04
Shaft Deflections ........ 13–12
Loading and Friction of Journal Bearings ........ 13–15
Current Practice in Bearing Loading and Clearance ........ 13–31
Thrust Bearings ........ 13–33
Perfect Lubrication of Bearings ........ 13–44
Miscellaneous Bearings ........ 13–48
Bearing Materials ........ 13–49
Finish of Bearing Metal Surfaces ........ 13–50
Lubrication of Bearings ........ 13–51

### Lubricants

Types of Lubricants ........ 13–52
Properties of Lubricants ........ 13–53
Lubricating Oil Requirements ........ 13–54
Selection of Mineral Lubricating Oil ........ 13–55

### Ball Bearings

Ball Bearing Standards ........ 13–59
Ball Bearing Types ........ 13–59
Design Practice ........ 13–61
Selection of Bearing Size ........ 13–71
Reference Rating ........ 13–72
Design Life and Service Life ........ 13–74
Practice in Mounting Ball Bearings ........ 13–75
Lubrication of Ball Bearings ........ 13–78
Cylindrical and Spherical Roller Bearings ........ 13–79
Typical Applications ........ 13–81

### Roller Bearings

Straight Roller Bearings ........ 13–82
Needle Bearings ........ 13–85
Tapered Roller Bearings ........ 13–89

## SECTION 14—GEARING

Friction Gearing ........ 14–02
Toothed Wheel Gearing ........ 14–04
Forms of the Teeth ........ 14–06
Rules for Calculating the Speed of Gears ........ 14–11
Elliptical Gears ........ 14–11
Epicyclic Gear Trains ........ 14–12
Internal Gear Drives ........ 14–14
Strength of Spur Gears ........ 14–14
Non-metallic Gears ........ 14–17
Efficiency of Spur Gears ........ 14–18
Helical Gears ........ 14–18
Bevel Gearing ........ 14–21
Screw Gearing ........ 14–25
Spiral Gear Drives ........ 14–26
Worm Gear Drives ........ 14–28
Materials of Gears ........ 14–35

Saws 22–35
Knives and Cutters 22–35
Boring Tools 22–37
Mortising Tools 22–39

### Machine Tools for Wood

Saw Machines 22–39
Planing Machines 22–40
Routers 22–44
Shaping Machines 22–44
Carving Machines 22–44
Boring Machines 22–45
Turning Machines 22–45
Mortising Machines 22–46
Double-end Tenoners 22–46
Sanders 22–47

## SECTION 23—MATERIALS HANDLING

### Hoisting

Manila Rope Hoisting 23–03
Wire Rope Hoisting 23–04

### Handling Material in Bulk

Wire Rope Haulage 23–13
Locomotive Cranes 23–17
Grab Buckets 23–20
Lifting Magnets 23–22

### Cranes and Derricks

Types of Cranes 23–23
Power Required to Drive Cranes 23–31
Loading and Unloading Equipment 23–33

### Hoists

Hand-operated Hoists 23–36
Electric Hoists 23–41
Power-operated Hoists 23–44

### General Conveying and Elevating

Coal Handling in Boiler Houses 23–46
Carriers and Elevators 23–50
Ash Handling 23–57
Elevators for Materials other than Coal 23–57
Coal Conveying in the Mine 23–58
BELT CONVEYORS 23–61
SCREW CONVEYORS 23–65
PNEUMATIC AND HYDRAULIC CONVEYING 23–67
PACKAGE HANDLING 23–71

### Vehicles

Tiering Machines, Lift Trucks and Skids 23–74
Electric Trucks and Tractors 23–76
MANUFACTURERS OF MATERIAL HANDLING EQUIPMENT 23–81

# TABLE OF CONTENTS

## SECTION 24—MECHANICAL POWER TRANSMISSION

### Shafting

PAGE
Horsepower Transmitted by Shafting 24–03
Deflection of Shafting 24–04
Flexible Shafting 24–05
Shaft Hangers 24–05

### Pulleys

Proportion of Pulleys 24–08
Cone Pulleys 24–08

### Belt Drives

Theory of Power Transmission by Belting 24–14
Horsepower of Leather Belts 24–16
Belt Maintenance 24–20
Belt Joints 24–22
Arrangement of Belt Drives 24–24
Short Center Drives 24–28
Belt Data 24–35
Miscellaneous Types of Belts 24–37

### Chain Drives

PAGE
Roller Chains 24–38
Silent Chains 24–45

### Rope Driving

Manila and Cotton Rope Drives 24–48
Wire Rope Drives 24–53

### Couplings and Clutches

Couplings 24–54
Clutches 24–61

### Speed Changing Mechanisms

Speed Reducers 24–69
Variable Speed Drives 24–72
Hydraulic Drives 24–79

### Dynamometers

Traction Dynamometers 24–82
The Prony Brake 24–82
Absorption Dynamometers 24–83
Transmission Dynamometers 24–84

## SECTION 25—ELECTRIC MOTORS AND THEIR CONTROL

### Electric Motors

Definitions 25–03
Application of Motors and Their Control 25–06
General Characteristics 25–10
Small Power Motors 25–18
Single-phase Large Power Motors 25–23
Polyphase Induction Large Power Motors 25–28
Polyphase Synchronous Large Power Motors 25–39
Direct-current Large Power Motors 25–44
Motor Applications 25–49

### Electric Motor Control

General Considerations 25–51
Control for Single-phase Motors 25–53
Control for Polyphase Induction Motors 25–54
Control for Direct-current Motors 25–57
Control for Synchronous Motors 25–59

## SECTION 26—MISCELLANEOUS SHOP EQUIPMENT

### Dust Collection

Characteristics of Dust 26–03
Types of Dust Collectors 26–04
Dust Collecting Systems 26–07
Cement Mill Dusts 26–11
Boiler Fly Ash 26–11

### Illumination

The Science of Lighting 26–12
Definitions 26–12
Units of Brightness 26–13
General and Localized Lighting 26–14
Foot-candles and Foot-candle Levels 26–15

## SECTION 27—SAFETY ENGINEERING

Accident Prevention 27–03
Mechanical Power Transmission 27–03
General Machinery 27–05
Woodworking Machinery 27–06
Metal Working Machinery 27–07
Miscellaneous Machinery and Equipment 27–07
Electrical Hazards 27–08
Industrial Buildings and Plants 27–09
Eye Protection and Safe Clothing 27–09
First Aid 27–10
Supervision and Education 27–10
Organizations 27–11

## SECTION 28—MATHEMATICAL TABLES

Logarithms 28–03
Hyperbolic Logarithms 28–23
Properties of Numbers—Decimal Equivalents, Squares, Cubes, Three-halves Powers, Square Roots, Cube Roots, Fifth Roots, Reciprocals, Circumferences and Areas of Circles 28–25
Circular Arcs, Chords, Sectors and Segments 28–41
Factors for Areas of Segments 28–43
Radians 28–44
Circumferences and Areas of Circles, Diameters in Feet and Inches 28–45
Natural Trigonometrical Functions 28–46
Logarithmic Trigonometrical Functions 28–49
Inches Expressed as Decimal of a Foot 28–49
Temperature Conversion Tables 28–50
Weights and Measures 28–52
The Metric System 28–53
Metric Equivalents 28–54

# SYMBOLS AND ABBREVIATIONS

## Greek Letters

| | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| Α | α | Alpha | Η | η | Eta | Ν | ν | Nu | Τ | τ | Tau |
| Β | β | Beta | Θ | ϑ θ | Theta | Ξ | ξ | Xi | Υ | υ | Upsilon |
| Γ | γ | Gamma | Ι | ι | Iota | Ο | ο | Omicron | Φ | φ | Phi |
| Δ | δ | Delta | Κ | κ | Kappa | Π | π | Pi | Χ | χ | Chi |
| Ε | ϵ | Epsilon | Λ | λ | Lambda | Ρ | ρ | Rho | Ψ | ψ | Psi |
| Ζ | ζ | Zeta | Μ | μ | Mu | Σ | σ ς | Sigma | Ω | ω | Omega |

## Mathematical Signs and Abbreviations

$+$ plus (addition).
$+$ positive.
$-$ minus (subtraction).
$-$ negative.
$\pm$ plus or minus.
$\mp$ minus or plus.
$=$ equals.
$\geqq$ equals or greater than.
$\leqq$ equals or is less than.
$\approx$ approximately equals.
$\times$ multiplied by.
$ab$ or $a.b = a \times b$.
$\div$ divided by.
$/$ divided by.
$\frac{a}{b} = a/b = a \div b$. $15/16 = \frac{15}{16}$.
$0.2 = \frac{2}{10}$; $0.002 = \frac{2}{1000}$.
$\sqrt{\ }$ square root.
$\sqrt[3]{\ }$ cube root.
$\sqrt[4]{\ }$ 4th root.
: is to, : : so is, : to (proportion).
2 : 4 : : 3 : 6, 2 is to 4 as 3 is to 6.
: ratio; divided by.
2 : 4, ratio of 2 to 4 = 2/4.
$>$ greater than.
$<$ less than.
° degrees, arc or thermometer.
′ minutes or feet.
″ seconds or inches.
′ ″ ‴ accents to distinguish letters, as $a'$, $a''$, $a'''$.
$a_1$, $a_2$, $a_3$, $a_b$, $a_c$, read $a$ sub 1, $a$ sub $b$, etc.
( ) [ ] { } —— parentheses, brackets, braces, vinculum; denoting that the numbers enclosed are to be taken together; as, $(a + b)c = \overline{4 + 3} \times 5 = 35$.
$a^2$, $x^3$, $a$ squared, $a$ cubed.
$a^n$, $a$ raised to the $n$th power.
$a^{2/3} = \sqrt[3]{a^2}$, $a^{3/2} = \sqrt{a^3}$.
$a^{-1} = \frac{1}{a}$, $a^{-2} = \frac{1}{a^2}$.
$10^9$ = 10 to the 9th power = 1,000,000,000.
$\sin a$ = the sine of $a$.
$\sin^{-1} a$ = the arc whose sine is $a$.
$\sin a^{-1} = \frac{1}{\sin a}$.
log = logarithm.
$\log_e$ or hyp log = hyperbolic logarithm.
% per cent.
∠ angle.
△ triangle.
sin, sine.
cos, cosine.
tan, tangent.
sec, secant.
versin, versed sine.
cot, cotangent.
cosec, cosecant.
covers, co-versed sine.

In Algebra, the first letters of the alphabet, $a$, $b$, $c$, $d$, etc., are generally used to denote known quantities, and the last letters, $w$, $x$, $y$, $z$, etc., unknown quantities.

*Abbreviations and Symbols commonly used.*

$d$, differential (in calculus).
$\int$, integral (in calculus).
$\int_b^a$, integral between limits $a$ and $b$.
Δ, delta, difference.
Σ, sigma, sign of summation.
$\pi$, pi, ratio of circumference of circle to diameter = 3.14159.
$g$, acceleration due to gravity = 32.16 ft. per second per second.

# GENERAL PROPERTIES OF MATERIALS

## 1. THE CHEMICAL ELEMENTS AND COMPOUNDS

Table 1 gives a list of the chemical elements, together with their atomic numbers and their atomic weights. The atomic weights are the 1934 weights published by the Committee on Atomic Weights of the International Union of Chemistry. Table 2, from Peele's Mining Engineers' Handbook, gives the chemical composition of the more important industrial compounds together with their molecular weights and specific gravity. Other properties of many of these compounds are discussed elsewhere in this volume and in Kent's Mechanical Engineers' Handbook—Power, comprising Vol. 2 of this series. For a complete discussion of the combinations and reactions of the more important of the chemical elements, and of chemical calculations, see Eshbach, Handbook of Engineering Fundamentals, Sec. 10, comprising Vol. 1 of this series.

**Table 1.—The Chemical Elements**

From report of Committee on Atomic Weights of Int. Union of Chemistry, 1934

## 2. PROPERTIES OF MATERIALS

**METALS.**—The properties of the metals used in engineering are given in Table 3 and the notes accompanying it. Many of these metals, particularly the ferrous metals, and the more generally used non-ferrous alloys also are discussed in great detail in other sections of this book, as indicated in the notes.

**NON-METALLIC MATERIALS.**—For properties of non-metallic materials, see pp. 5–03 to 5–38.

**WOOD.**—For properties of wood, see p. 5–20.

### Table 2.—The More Important Industrial Compounds

| Name | Formula | Mol. wt. | Sp. gr. |
|---|---|---|---|
| Acetic acid | $HC_2H_3O_2$ | 60.03 | 1.06 |
| Alcohol (grain) | $C_2H_5\cdot OH$ | 46.05 | 0.785 |
| " (wood) | $CH_3\cdot OH$ | 32.03 | 0.791 |
| Alumina | $Al_2O_3$ | 102.2 | 3.86 |
| Alum, ammonium | $Al_2(SO_4)_3\cdot (NH_4)_2SO_4\cdot 24\,H_2O$ | 906.95 | 1.64 |
| " potassium | $Al_2(SO_4)_3\cdot K_2SO_4\cdot 24\,H_2O$ | 949.06 | 1.76 |
| Ammonia | $NH_4OH$ | 35.03 | 0.88 |
| Am chlor (sal-ammoniac) | $NH_4Cl$ | 53.50 | 1.52 |
| Ammonium nitrate | $NH_4NO_3$ | 80.05 | 1.73 |
| " sulphate | $(NH_4)_2SO_4$ | 132.14 | 1.77 |
| Arsenious oxide (white arsenic) | $As_4O_6$ | 395.84 | 3.74 |
| Barium carbonate | $BaCO_3$ | 197.37 | 4.27 |
| " sulphate (blanc fixe) | $BaSO_4$ | 233.44 | 4.40 |
| Boric acid | $H_3BO_3$ | 62.02 | 1.43 |
| Calcium acetate (acet. of lime) | $Ca(C_2H_3O_2)_2.\,H_2O$ | 176.13 | ...... |
| Calcium carbide | $CaC_2$ | 64.07 | 2.22 |
| " carbonate | $CaCO_3$ | 100.07 | 2.85 |
| " oxide (quicklime) | $CaO$ | 56.07 | 3.30 |
| " hydroxide (slaked lime) | $Ca(OH)_2$ | 74.09 | 2.08 |
| " phosphate (phos. of lime) | $Ca_3(PO_4)_2$ | 310.28 | 3.18 |
| " sulphate (plaster paris) | $CaSO_4$ | 136.14 | 2.96 |
| Carbon tetrachloride | $CCl_4$ | 153.84 | 1.58 |
| " disulphide | $CS_2$ | 76.14 | 1.29 |
| Cupric arsenite (paris green) | $CuHAsO_3$ | 187.54 | ...... |
| Cupric oxide | $CuO$ | 79.57 | 6.37 |
| " sulphate (bluestone) | $CuSO_4\cdot 5H_2O$ | 249.72 | 2.28 |
| Ferric oxide | $Fe_2O_3$ | 159.68 | 5.18 |
| Ferrous oxide | $FeO$ | 71.84 | ...... |
| " sulphate (copperas) | $FeSO_4\cdot 7H_2O$ | 278.02 | 1.90 |
| Hydrochloric acid | $HCl$ | 36.47 | ...... |
| Hydrogen peroxide | $H_2O_2$ | 34.02 | ...... |
| Lead acetate (sugar of lead) | $Pb(C_2H_3O_2)_2\cdot 3\,H_2O$ | 379.20 | 2.50 |
| Lead carbonate (white lead) | $2PbCO_3\cdot Pb(OH)_2$ | 775.31 | ...... |
| Lead monoxide (litharge) | $PbO$ | 223.10 | 9.37 |
| " oxide (red lead) | $Pb_3O_4$ | 685.30 | 9.10 |
| " sulphate | $PbSO_4$ | 303.17 | 6.23 |
| Magnesium carbonate | $MgCO_3$ | 84.32 | 3.04 |
| " sulph. (epsom salt) | $MgSO_4\cdot 7\,H_2O$ | 246.50 | 1.68 |
| Manganese dioxide | $MnO_2$ | 86.93 | 5.03 |
| Mercuric chlor. (corrosive sublimate) | $HgCl_2$ | 271.52 | 5.40 |
| Nitric acid | $HNO_3$ | 63.02 | 1.53 |
| Phosphoric acid | $HPO_3$ | 80.05 | 2.30 |
| Potassium carbonate (potash) | $K_2CO_3\cdot 2\,H_2O$ | 174.23 | 2.04 |
| Potassium chlorate | $KClO_3$ | 122.56 | 2.34 |
| " chloride | $KCl$ | 74.56 | 1.99 |
| " chromate | $K_2CrO_4$ | 194.20 | 2.73 |
| " cyanide | $KCN$ | 65.11 | 1.52 |
| " ferricyanide | $K_3Fe(CN)_6$ | 329.20 | 1.81 |
| " ferrocyanide | $K_4Fe(CN_6)\cdot 3\,H_2O$ | 422.35 | 1.85 |
| " hydroxide (caustic potash) | $KOH$ | 56.11 | 2.04 |
| " nitrate (saltpeter) | $KNO_3$ | 101.11 | 2.10 |
| " permanganate | $KMnO_4$ | 158.03 | 2.70 |
| " sulphate | $K_2SO_4$ | 174.27 | 2.66 |
| Silver nitrate (lunar caustic) | $AgNO_3$ | 169.89 | 4.35 |
| Sodium borate (borax) | $Na_2B_4O_7\cdot 10\,H_2O$ | 382.16 | 1.69 |
| " carbonate (soda) | $Na_2CO_3$ | 106.00 | 2.47 |
| " bicarbonate | $NaHCO_3$ | 84.01 | 2.20 |
| " chloride (salt) | $NaCl$ | 58.46 | 2.17 |
| " cyanide | $NaCN$ | 49.01 | ...... |
| " hydroxide (caustic soda) | $NaOH$ | 40.01 | 2.13 |
| " nitrate (Chile saltpeter) | $NaNO_3$ | 85.01 | 2.27 |
| " silicate (water glass) | $Na_2Si_4O_9$ | 303.20 | ...... |
| " sulphate (Glauber salts) | $Na_2SO_4\cdot 7\,H_2O$ | 268.18 | ...... |
| " sulphite | $Na_2SO_3\cdot 7\,H_2O$ | 252.18 | 1.59 |
| " thiosulphate | $Na_2S_2O_3\cdot 5H_2O$ | 248.22 | 1.73 |
| Sulphur dioxide | $SO_2$ | 64.07 | ...... |
| Sulphuric acid | $H_2SO_4$ | 98.09 | ...... |
| Tartaric acid | $H_2C_4H_4O_6$ | 150.05 | 1.75 |
| Tin chloride | $SnCl_4$ | 260.84 | 2.28 |
| Vanadium oxide | $V_2O_5$ | 182.00 | 3.36 |
| Zinc chloride | $ZnCl_2$ | 136.29 | 2.91 |
| " oxide (zinc white) | $ZnO$ | 81.37 | 5.78 |
| " sulphate | $ZnSO_4\cdot 7\,H_2O$ | 287.55 | 1.97 |

## Notes for Table 3

1. **Aluminum.**—The lightest of all useful metals except beryllium and magnesium, soft ductile and malleable. Color, white with a bluish cast. Very non-corrosive. Strength varies widely, depending on the alloying materials and treatment. For further properties, see p. 4–25 to 4–49.

2. **Antimony.**—A brittle metal of bluish-white color, and highly crystalline or laminated structure. Burns in air with a bluish-white flame. Chiefly used for manufacturing such alloys as type-metal (antimony 1, lead 4), brittania (antimony 1, tin 9), and various anti-friction metals. Commercial antimony contains minute quantities of silver, arsenic, tin, lead, copper, iron, nickel, cobalt and sulphur.

3. **Arsenic.**—A chemical element midway between the metals and non-metals. It occurs in nature in combination with many metals and with sulphur. Arsenic compounds are used in the laboratory for titrating iodine solutions. Used in industry in dyeing, and vermin- and insect-poisoning compounds. Also used in medicine. Its soluble compounds are extremely poisonous.

4. **Barium.**—A metal used in the manufacture of pigments and in pyrotechnic compounds. Also has been used in the commercial preparation of oxygen.

5. **Beryllium.**—A light metal of silvery luster used in the production of light alloys. Will not decompose in water at any temperature below 212° F.

*(Continued on page 1-08)*

* A subscript after a character indicates the number of times it is repeated; thus $0.0_38 = 0.0008$.

† Value uncertain; temperatures above melting point of platinum may be 100° F. in error.

‡ Dr.-Ing. P. Oberhoffer, in *Zeit.* des Vereines Deutscher Ingenieure (*Eng. Digest*, Sept., 1908), describes some experiments on the specific heat of nearly pure iron. The following mean specific heats were obtained:

| Temp., deg. F. | 500 | 600 | 800 | 1000 | 1200 | 1300 |
|---|---|---|---|---|---|---|
| Specific Heat | 0.1228 | 0.1266 | 0.1324 | 0.1388 | 0.1462 | 0.1601 |
| Temp., deg. F. | 1500 | 1800 | 2100 | 2400 | 2700 | |
| Specific Heat | 0.1698 | 0.1682 | 0.1667 | 0.1662 | 0.1666 | |

The specific heat increases steadily between 500° and 1200° F. Then it increases rapidly to 1400° F., after which it remains nearly constant.

§ $R_t = R_0(1 + 0.0_3494t + 0.0_5555t^2)$

**6. Bismuth.**—Color, light red. Highly crystalline, and so brittle that it can readily be pulverized. Expands in cooling. Tribe has shown that this expansion does not occur until after solidification. Bismuth is the most diamagnetic element known, a sphere of it being repelled by a strong magnet. Chiefly used in fusible alloys for electric fuses, plugs for automatic fire alarms and automatic sprinkler systems, and as stereotype metal in the printing industries.

**7. Brass and Bronze.**—Alloys of copper, tin, zinc and other metals, covering a wide range of properties and uses, depending on the proportions of the alloying metals and upon the method of manufacture and treatment. See pp. 4–18 to 4–33.

**8. Cadmium.**—Color bluish-white, lustrous, with a fibrous fracture. Used as an ingredient in some fusible alloys with lead, tin, and bismuth. Alloys of cadmium are used for the fusible tips of automatic sprinklers, safety fusible plugs for boilers, cadmium cliché metal for stereotype plates, and solders in which cadmium is substituted for part or all of the tin commonly used. A fraction of 1% cadmium is used as a deoxidizer for bronze telephone and telegraph wires and cables in Europe. It is also used as a deoxidizer in making nickel alloys. It is a better rust preventive than nickel and it may be used in combination with nickel in nickel plating, the first coat consisting of cadmium and the second coat of tarnish-proof nickel.

**9. Calcium.**—A metal found in nature in the form of carbonate, limestone, marble, chalk, dolomite, gypsum, etc. Metallic calcium is used in an alloy for anti-friction metals for bearings. The carbonate is used in the preparation of the pigment whiting used in the paint and paper industries. Calcium bicarbonate is the cause of temporary hardness in water and calcium sulphate causes permanent hardness.

**10. Chromium.**—A steel-white metal, harder than iron, copper, or nickel, and capable of taking a brilliant polish. In the massive form it is not affected by moisture, air, and only very slightly by dilute acids. Now produced on a large scale for use in stainless and alloy steels. Also used as a protective surface for metals in the form of plate. Chromuim compounds are used in the manufacture and application of dyes and pigments, tanning hides, and photography.

**11. Cobalt.**—A silver-white metal, slightly harder than iron or nickel. Magnetic, in all temperatures up to 2100° F., then becoming non-magnetic. When polished is not appreciably affected by exposure to air or water. Dissolves in nearly all dilute acids, evolving hydrogen. Is not attacked by alkali solutions or fused alkalies. Used in the manufacture of ferrous and non-ferrous alloys. Steel containing cobalt and tungsten is used in permanent magnets for telephony. Non-ferrous alloys containing over 50% cobalt with varying amounts of tungsten, chromium, and occasionally molybdenum are used in high-speed cutting tools (see p. 21–25).

**12. Copper.**—See p. 4–09.

**13. Gold.**—The most malleable and ductile of all metals. One ounce Troy may be beaten so as to cover 160 sq. ft. of surface. The average thickness of gold leaf is 1/282000 in. or 100 sq. ft. per ounce. One grain may be drawn into a wire 500 ft. long. Ductility is destroyed by the presence of 1/2000 part of lead, bismuth or antimony. Gold is hardened by the addition of silver or copper. By jewelers, the fineness of gold is expressed in carats, pure gold being 24 carats, $^{3}/_{4}$ fine, 18 carats, etc.

**14. Indium.**—A white, lustrous metal, very soft and ductile. Has high surface stability at ordinary temperatures, but oxidizes and burns at temperatures above its melting point, especially if finely divided. Can be electroplated, simultaneously with other elements, from a sulphuric acid bath containing sodium citrate. Its addition to other metals increases their surface stability and hardness until the In is in excess. Of use in the automotive, electrical, jewelry, silverware, and dental industries. See article by W. S. Murray, *Ind. & Engg. Chem.*, June, 1932.

**15. Iridium.**—One of the rarer metals. Has a white luster, resembling that of steel. Is quite brittle when cold, but at white heat is somewhat malleable. Is extremely infusible and almost absolutely inoxidizible. For uses of iridium, methods of manufacturing it, etc., see W. L. Dudley, Iridium Industry, *Trans.*A.I.M.E., 1884.

**16. Iron.**—For discussion of the properties of iron, see p. 2–03; of cast iron, see p. 2–03, and Foundry Practice, p. 20–03; of wrought iron, see p. 2–04; of steel, see pp. 2–12 to 2–48.

**17. Lead.**—Brittle just below the melting point, with a crystalline fracture, malleable and ductile. Tenacity so low that it can be drawn into wire only with difficulty. Elasticity is low, and the metal flows under very slight stress. Rendered brittle, and easily fusible by the presence of antimony and arsenic. Penn. R. R. specifications call for not less than 99 $^{1}/_{2}$% metallic lead in No. 1 grade, and not less than 97 $^{1}/_{2}$% metallic lead for No. 2 grade. Shrinkage in casting, 0.3125 in. per ft.

**18. Magnesium.**—Color, brilliant silver-white. Slightly malleable when cold, but very malleable and ductile at 660° F. Can be cast in iron molds or dry sand, and extruded into shapes or wire at 1022° F. Is stable in air at ordinary temperatures, but combines readily with oxygen and nitrogen at temperatures above its melting point. Is nearly non-corrosive, a film of oxide forming in the presence of moisture which prevents further oxidation. It is attacked by the acids $H_2SO_4$, $HNO_3$ and HCl, but is not attacked by alkalies. At red heat, it reduces CO, $CO_2$, $SO_2$, $SiO_2$ and most metallic oxides and many hydrocarbons. In form of filings, wire or ribbon it burns in air with a dazzling brilliancy, and is used for flash and signal lights. Its heat of combustion is 10,710 B.t.u. per lb. Alloys readily with aluminum, copper, nickel, zinc, tin, cadmium, silver, silicon and other non-ferrous metals. Principally used as a deoxidizer of non-ferrous metals, and for alloying with aluminum; 5% Mg added to aluminum gives about as much increase of strength and hardness as 10% of copper. Also used for laboratory reactions. See also p. 4–55.

**19. Manganese.**—The pure metal is not used in the arts, but alloys of manganese and iron (spiegeleisen, containing below 25% Mn, and ferro-manganese, containing 25 to 90% Mn) are used in the manufacture of steel. Metallic manganese when alloyed with iron, oxidizes rapidly in air. In steel manufacture it removes oxygen from the bath of steel.

**20. Mercury.**—A silver-white metal, liquid at temperatures above −38° F. Unchangeable as gold, silver and platinum in the atmosphere at ordinary temperatures, but oxidizes to the red oxide when near its boiling-point. Easily tarnished by sulphur fumes, also by dust, from which it may be freed by straining through cloth. No metal, except iron or platinum, should be allowed to touch mercury. The smallest portions of tin, lead, zinc and even copper to a less extent, cause it to tarnish and lose its perfect liquidity.

**21. Molybdenum.**—A silvery-white, malleable metal, softer than steel. Its tensile strength, drawn into wire, is about $^1/_2$ that of tungsten or steel wire of equivalent diameter. Is resistant to acids; concentrated $H_2SO_4$ and HCl attack it slowly, but moderately dilute $HNO_3$ and *aqua regia* dissolve it rapidly. Is attacked by fused, but not by liquid, caustic alkalies. Is not affected by air at ordinary temperatures, but oxide forms at a dull red heat. Used as a support for electric lamp filaments, windings for electric resistance furnaces, X-ray apparatus, wireless telegraphy plates, and for alloying with steels to produce high strength. Steels with 1% Mo are used for permanent magnets, rustless steels and high-speed tools. See also p. 4–60.

**22. Nickel.**—Color, silvery-white with a strong luster, not tarnishing in air. Ductile, hard, magnetic and as tenacious as iron. Loses its magnetic quality at 662° F. Can be welded to itself or to iron at a white heat. Resists cold sulphuric and hydrochloric acid, but is soluble in nitric acid or *aqua regia*. Chiefly used in alloys with copper, as German-silver, nickel-silver, etc., and also in the manufacture of steel to increase its hardness and strength; also used for nickel-plating. See also pp. 4–49 to 4–54.

**23. Platinum.**—Color, whitish steel-gray; malleable, very ductile, and as unalterable by ordinary agencies as gold. Fused and refined, it is as soft as copper. Fusible only by the oxy-hydrogen blowpipe or strong electric currents. Combined with iridium, it forms an alloy of great hardness, which has been used for gun-vents, and for standard weights and measures. The most important uses of platinum in the arts are for vessels for chemical laboratories and manufactories, and for the connecting wires in incandescent electric lamps, and for electrical contact points. Cubical expansion less than that of any other metal except the rare metals, and almost the same as glass.

**24. Potassium.**—A metal forming the basis of many fertilizers.

**25. Silver.**—Whitest of all metals, very malleable and ductile.

**26. Sodium.**—One of the alkali metals used in the preparation of important organic compounds, dyes, medicinal substances and perfumes. Becomes an important reducing agent when alloyed with mercury. Sodium and potassium hydroxides are known as caustic alkalies or lye.

**27. Steel.**—A compound of iron and carbon, containing up to 1.7 carbon. Alloyed with other metals, it covers a wide range of properties and uses. For properties, uses and treatment of steel, see pp. 2–12 to 2–48. For properties and treatment of tool steel, see p. 21–25.

**28. Tantalum.**—Has a modulus of elasticity of 27,000,000. The pure metal can be hammered into thin sheets or drawn into fine wire. Has the hardness of soft steel, and a tensile strength higher than steel or platinum. The coefficient of expansion is less than that of platinum, and it can be sealed into glass. At temperatures below 572° F., pure tantalum will resist all acids except fluoric.

**29. Tin.**—White, lustrous, soft, malleable. Not sensibly volatile when at ordinary temperature. Malleability decreases with increase of temperature, until at about 390° F. it is very brittle. The presence of 1 to 2% of copper or lead increases its hardness. Chief uses are for coating of sheet-iron (called tin-plate) and for making alloys with copper and other metals. Commercial tin contains copper, iron, bismuth and other impurities.

**30. Tungsten.**—A bright, steel-gray metal, hard but so ductile that it may be drawn into very fine wire. Its chief use is for filaments of incandescent electric lamps. It is also used as an alloy in high-speed tool-steel, as it increases the hardness by keeping the carbon in solution. Its presence in high-carbon steels increases the magnetic retentivity, and it therefore is used in the steel of permanent magnets. See also p. 4–58.

**31. Zinc.**—Color, bluish-white; ductile and malleable. Volatilizes and burns in air when melted, with bluish-white fumes of zinc oxide. Compressive strength about 20,000 lb. per sq. in. Shrinkage in casting 0.3125 in. per ft. Is practically non-corrosive in air, a thin film of carbonate of zinc forming upon it. Its principal uses are for coating iron surfaces, called "galvanizing," and for making brass and other alloys. For additional properties of zinc and zinc alloys see pp. 4–10 to 4–13.

## 3. SPECIFIC GRAVITY

**THE SPECIFIC GRAVITY** of a solid or liquid substance is the ratio of the mass of a given volume of the substance to the mass of an equal volume of water at some standard temperature. The temperature commonly used in engineering work is 60° F. The temperature used by physicists is 4° C. In the metric system the specific gravity is equal to the density, *i.e.*, to the weight in grams of one cubic centimeter.

The specific gravity of gases is taken as the ratio of the masses of equal volumes of the given gas and of air or hydrogen, usually at 32° F. and 29.921 in. of mercury barometric pressure (0° C. and 760 mm. pressure). It is necessary to state which basis is used, *i.e.*, air = 1, or hydrogen = 1.

**Determination of Specific Gravity of Solids.**—Determine the weight of the body in air; then submerge it in water and determine its weight. If $W$ = weight in air, and $w$ = weight when submerged,

$$\text{Specific gravity} = W/(W - w).$$

If the body is lighter than water, attach to it a weight, $w_1$, sufficient to sink it. Then

$$\text{Specific gravity} = (W - w_1)/\{(W - w_1) - w\}.$$

Given the specific gravity, referred to water at 60° F.,

$$\text{Weight per cu. ft.} = \text{sp. gr.} \times 62.36.$$
$$\text{Weight per cu. in.} = \text{sp. gr.} \times 0.036088.$$
$$\text{Specific gravity} = \text{weight per cu. ft.} \times 0.016036.$$

**THE HYDROMETER.**—The hydrometer is an instrument for determining the density of liquids. It usually is made of glass, and consists of three parts: (1) the upper part, a graduated stem or fine tube of uniform diameter; (2) a bulb, or enlargement of the tube, containing air; and (3) a small bulb at the bottom, containing shot or mercury which causes the instrument to float in a vertical position. The graduations are figures representing either specific gravities, or the numbers of an arbitrary scale, as the Baumé, A.P.I., Twaddell or Beck.

**The Baumé Hydrometer Scale** is based on the following formulas:

For liquids lighter than water

$$\text{Specific gravity} = 140/(130 + \text{degrees Baumé})$$

For liquids heavier than water

$$\text{Specific gravity} = 145/(145 - \text{degrees Baumé})$$

The relation of the two Baumé scales to the specific gravity, together with the corresponding weights per U. S. gallon, is given in Table 4.

**The A.P.I. Hydrometer Scale** was adopted to avoid the confusion incident to two Baumé scales, and is recommended by the American Petroleum Institute, the U. S. Bureau of Mines and the U. S. Bureau of Standards for use in the petroleum and oil industries. It is based on the formula

$$\text{Degrees A.P.I.} = 141.5/(\text{Sp. gr. } 60°/60° \text{ F.}) - 131.5.$$

The relation of the A.P.I. scale to specific gravity and the corresponding weights per U. S. gallon are given in Table 5.

**Beck Hydrometer Scale.**—The relation between specific gravity and the Beck hydrometer scale is expressed by the formulas:

For liquids heavier than water, $\text{Sp. Gr.} = 170 \div (170 - \text{Beck degrees})$

For liquids lighter than water, $\text{Sp. Gr.} = 170 \div (170 + \text{Beck degrees})$

**Twaddell Hydrometer Scale.**—The relation between specific gravity and the Twaddell hydrometer scale, used only for liquids heavier than water, is expressed by the formula

$$\text{Sp. Gr.} = (5 \times \text{Twaddell degrees} + 1000) \div 1000.$$

**The Salinometer** is a hydrometer used for determining the density of brine solutions. The indications are 4 times as large as those on the corresponding Baumé scale.

**Table 4.—Specific Gravities at 60°/60° F. Corresponding to Degrees Baumé**

**SPECIFIC GRAVITY OF VARIOUS SUBSTANCES.**—The specific gravity of the useful metals is given in Table 3. Table 6 gives the specific gravity of various solids, except the metals and woods, and Tables 7 and 8 give the specific gravity of liquids and gases respectively. For specific gravity of the various woods, see p. 5–21.

### Table 6.—Specific Gravity and Weight of Solid Substances, Except Metals and Wood

| Substance | Specific Gravity | Average Weight, lb. per cu. ft. | Substance | Specific Gravity | Average Weight, lb. per cu. ft. |
|---|---|---|---|---|---|
| Asbestos | 2.1–2.8 | 153 | Gypsum | 2.08–2.4 | 140 |
| Ashes | ....... | 43 | Hornblende | 3.2–3.52 | 210 |

* This column gives the ratio of specific heat at constant pressure to specific heat at constant volume.

## 4. HARDNESS

Hardness of a substance may be defined as its resistance to penetration by another substance. Several methods of determining hardness are in commercial use. These methods are described below.

**BRINELL'S METHOD.**—J. A. Brinell, a Swedish engineer, in 1900 published information about a method for determining the relative hardness of steel, which has come into extensive use. A hardened steel ball, 10 mm. diam. (0.3937 in.), is forced with a pressure of 3000 kg., or 500 kg. for soft metals, into a flat surface on the sample to be tested and allowed to remain on iron and steel for at least 10 seconds, and on other metals for at least 30 sec., to make a slight spherical indentation, whose diameter is measured with a microscope. The hardness is defined as the quotient of the pressure divided by the area of the indentation. From the measurement the *hardness number* is calculated by the equation

$$B = P/(\pi D/2)(D - \sqrt{D^2 - d^2}),$$

where $P$ = load = 3000 kg.; $D$ = diam. of ball = 10 mm.; $d$ = diam. of indentation, mm.; $B$ = Brinell hardness number. Table 3 gives the hardness numbers corresponding to the different values of $d$. A complete table of these numbers is given in A.S.T.M. Standards, 1933 E10–27, pp. 943–944.

There is a well defined approximate relationship between the Brinell numbers and the ultimate strength of the steel. Abbott (*Proc.* A.S.T.M. vol. xv, Pt. II, 1915), as the result of a large number of tests of different kinds of steel, proposed the equation $s_u = 0.70B - 26$, where $s_u$ = ultimate strength in thousands of lb. per sq. in.; $B$ = Brinell hardness number. For many steels, however, the strength is as well represented by the relation $s_u = 0.50B$.

**THE ROCKWELL METHOD** is similar to the Brinell method, in that it forces a spherical point into the metal to be tested and measures the penetration of the point. For metals of average hardness, as mild steel, the point is $^1/_{16}$ in. diam. and the load is 100 kg. (Rockwell B test); for harder metals a conical diamond point is used with a load of 150 kg. (Rockwell C test). The Rockwell hardness number is read directly from a numbered dial. One advantage of the Rockwell over the Brinell is that a smaller indentation is produced. The ultimate tensile strength of steel, $s_u$, is given in thousands of lb. per sq. in. by the equation $s_u = 3750/(130 - R_B)$, $R_B$ being the number read from the dial of the instrument (B test).

**THE VICKERS PYRAMID HARDNESS TESTING MACHINE** is a British instrument in which the principle employed is the same as that in the Brinell and Rockwell machines. The operation differs, in that the penetrator is a diamond in the form of a pyramid. By means of a microscope attachment, measurements are made of the distance across the diagonal of the indentation. One of the advantages of this machine is that it is suitable for any degree of hardness.

**THE SCLEROSCOPE,** invented by A. F. Shore, consists chiefly of a vertical glass tube in which slides freely a small cylinder of very hard steel, pointed on the lower end, called the hammer. This hammer is allowed to fall about 10 in. on the sample to be tested. The distance it rebounds is taken as a measure of the hardness of the sample. A scale on the tube is divided into 140 equal parts, and the hardness is expressed as the number on the scale to which the hammer rebounds. Measured in this way the hardness of different substances is as follows: Glass, 130; porcelain, 120; hardest steel, 110; tool steel, 1% C, may be as low as 31; mild steel, 0.5 C, 26 to 30; gray iron castings, 39; wrought iron, 18; babbitt metal, 4 to 10; soft brass, 12; zinc, 8; copper, 6; lead, 2. (*Cass. Mag.*, Sept., 1908.) The relationship between the Scleroscope number and the ultimate tensile strength, $s_u$ is given by Abbott (*Proc.* A.S.T.M., vol. xv, Pt. II, 1915) by the equation $s_u = 4.0S - 15$, where $s_u$ is in thousands of lb. per sq. in. and $S$ is the Scleroscope number.

**RELATIONSHIP BETWEEN DIFFERENT HARDNESS NUMBERS.**—A rational relation exists between the Brinell and Rockwell numbers, and also between these numbers and the Vicker's Pyramid numbers; an empirical relation exists also between the foregoing numbers and those of the Shore scleroscope. Petrenko (*Tech. Paper* No. 334, U. S. Bureau of Standards) gives the following equations:

$$B = 25{,}000/(100 - R_C) \text{ for } R_C > 40;$$

$$B = 1{,}420{,}000/(100 - R_C)^2 \text{ for } R_C \text{ from } -20 \text{ to } 40;$$

$$B = 7300/(130 - R_B) \text{ for } R_B \text{ from 35 to 100,}$$

where $B$ = Brinell number obtained with a 10 mm. ball and 3000-kg. load; $R_C$ = Rockwell number on the $C$ scale, using a 150-kg. load and a 120° diamond penetrator; $R_B$ = Rockwell number on the $B$ scale with a 100-kg. load and a $^1/_{16}$-in. ball.

Abbott (*Proc.* A.S.T.M., vol. xv, Pt, II, 1915) derives from tests the empirical relation $B = 5.5S - 28$, $B$ being the Brinell number and $S$ the scleroscope number. Table 9 gives these various hardness numbers in terms of each other. The values were obtained from the manufacturers of the instruments and from published experimental data. The scleroscope numbers, as tabulated, vary slightly from those given by the Sub-committee on Hardness Conversion of the A.S.S.T. in its 1930 handbook; the committee gives a scleroscope value of 81 for a Brinell number of 627 as compared with 84 in Table 9 (by interpolation), while the committee scleroscope number is 30 for a Brinell number of 197

**Table 9.—Conversion Table for Approximate Hardness Numbers**
(Compiled mainly from Manufacturers' Tables)

| Brinell 3000 kg. Load, 10-mm. Ball | | Rockwell Number | | Shore Scleroscope Number | Vicker's Pyramid Number | Brinell 3000 kg. Load, 10-mm. Ball | | Rockwell Number | | Shore Scleroscope Number | Vicker's Pyramid Number |
|---|---|---|---|---|---|---|---|---|---|---|---|
| Diam. of Indentation, mm. | Hardness Number | *C* Scale, 150 kg. Load, 120° Diamond Cone | *B* Scale, 100 kg. Load, 1/16-in. Ball | | | Diam. of Indentation, mm. | Hardness Number | *C* Scale, 150 kg. Load, 120° Diamond Cone | *B* Scale, 100 kg. Load, 1/16-in. Ball | | |
| 2.40 | 653 | 62 | ...... | 86 | 783 | 4.60 | 170 | ...... | 87 | 24 | 170 |
| 2.60 | 555 | 55 | ...... | 75 | 622 | 4.70 | 163 | ...... | 85 | 23 | 163 |
| 2.80 | 477 | 49 | ...... | 66 | 513 | 4.80 | 156 | ...... | 82 | 23 | 156 |

| 4.30 | 197 | ...... | 93 | 28 | 197 | 6.20 | 88.7 | ...... | 47 | .... | 88.7 |
| 4.40 | 187 | ...... | 91 | 27 | 187 | 6.30 | 85.5 | ...... | 44 | .... | 85.5 |
| 4.50 | 179 | ...... | 89 | 25 | 179 | 6.40 | 82.5 | ...... | 42 | .... | 82.5 |

as compared with 28 in Table 9. Both lists are the same for scleroscope number 54 which equals Brinell number 387.

**MOH'S SCALE OF HARDNESS** is a scratch hardness scale. It consists of a series of minerals, each of which can be scratched by the mineral next above it in the scale. The differences in the original Moh scale are not uniform and the intervals between successive numbers increase rapidly as the hardness number increases. The step from 9 to 10 probably is as great as from 1 to 9. Carborundum frequently is given 9.6, being, therefore, much harder than corundum but not so hard as a diamond. In order to make a more uniform scale, a modification of the Moh scale was proposed by Ridgeway, Ballard and Bailey (*Trans.* Am. Electrochem. Soc. vol. lxiii, p. 392, 1933), wherein industrial minerals are included, and which subdivided the wide spaces between 8 and 9, and 9 and 10 in the Moh scale. The original Moh scale and the modified scale, are as follows:

| Original | Modified | Original | Modified | Original | Modified |
|---|---|---|---|---|---|
| 1. Talc | 1. Talc | 6. Orthoclase | 6. Orthoclase or Periclase | | 10. Garnet |
| 2. Gypsum | 2. Gypsum | | | | 11. Fused Zirconia |
| 3. Calc spar | 3. Calc spar | | 7. Vitreous Pure Silica | 9. Sapphire | 12. Fused Alumina |
| 4. Fluor spar | 4. Fluor spar | | | | 13. Silicon Carbide |
| 5. Apatite | 5. Apatite | 7. Quartz | 8. Quartz | | 14. Boron Carbide |
| | | 8. Topaz | 9. Topaz | 10. Diamond | 15. Diamond |

Certain metals have almost the same behavior in the scratch test as some of the minerals in the modified scale. These are, with their scale numbers: 8, Stellite; 11, Tantalum carbide; 12, Tungsten carbide.

Table 10 gives the relative hardness of various materials, according to the Moh scale. Table 11 gives the hardness of certain chemical elements according to the same scale.

**Table 10.—Hardness of Various Materials by Moh Scale**
(Smithsonian Tables)

| Material | Hardness | Material | Hardness | Material | Hardness | Material | Hardness |
|---|---|---|---|---|---|---|---|
| Agate | 7.0 | Bismuth | 2.5 | Gypsum | 1.6–2.0 | Plat-iridium | 6.5 |

| Bell-metal | 4.0 | Graphite | 0.5–1.0 | Platinum | 4.3 | Wood's metal | 3.0 |

## 5. COMPRESSIBILITY

**COMPRESSIBILITY OF LIQUIDS.**—The coefficient of compression of a liquid is $\beta = (1/V_1) \times \{(V_1 - V_2)/(p_2 - p_1)\}$ where $V_1$ and $V_2$ are the volumes at the same temperature, deg. C., under pressures $p_1$ and $p_2$ (atmospheres) respectively. Values of $\beta \times 10^6$ are given in Table 11.

**Table 11.—Compressibility of Liquids**
(From Smithsonian Tables)

| Substance | $t$, deg. C. | Pressure, Atmospheres | $\beta \times 10^6$ | Substance | $t$, deg. C. | Pressure, Atmospheres | $\beta \times 10^6$ |
|---|---|---|---|---|---|---|---|
| Chloroform | 20 | ........ | 128 | Water | 20 | 1–25 | 49.1 |
| Alcohol, ethyl | 20 | 1–50 | 112 | “ | 20 | 25–50 | 47.6 |
| “ methyl | 18.1 | 8 | 120 | “ | 20 | 1–100 | 46.8 |

# IRON AND STEEL

**By Bradley Stoughton**

Iron is a chemical element, which in its pure form has almost no commercial use. Iron which has a purity of 98 to 99% is used commercially for certain special purposes. See p. 2–06. The addition of other elements to iron, as carbon, silicon, manganese, nickel, etc., completely changes its character and renders it the most useful metal known to man.

## 1. PIG IRON

Iron is smelted from the ore in the blast furnace, the resulting product being known as pig iron. Analyses of various grades of pig iron are given in Table 1.

**Foundry Pig Iron** is pig iron intended for foundry uses. The silicon content is high, and the sulphur content usually is low.

**Charcoal Pig Iron** is pig iron made in blast furnaces using charcoal as fuel. Sulphur content does not exceed 0.05%, and silicon also is low. Charcoal iron is preferred for chilled castings, low in sulphur, such as chilled car wheels, chilled iron rolls, etc.

**Acid Pig Iron** is a trade name for pig iron suitable for use in the Bessemer converter and the acid open-hearth furnace, for steel making. Phosphorus content must be low.

**Basic Pig Iron** is a trade name for pig iron of phosphorus content higher than that of acid pig iron, and silicon content lower than that of either acid or foundry pig iron. It usually contains 1.75–2% manganese.

**Forge Pig Iron** is pig iron suitable for use in the puddling furnace.

**Electric Pig Iron** is pig iron made directly from ore in the electric furnace.

## 2. CAST IRON

Pig iron, or iron direct from the blast furnace, ordinarily is unsuitable for iron castings without the admixture of other elements. Castings may be made with metal direct from the blast furnace, provided sufficient metal, melted in a cupola, and containing the necessary alloying elements to correct the composition of the blast furnace metal, is added to the latter. The usual practice of making iron castings is to remelt the pig iron, together

**Table 1.—Analyses of Pig Irons or Cast Irons**

Figures in bold-faced type indicate essential constituents; figures in light-faced type are approximately correct, but are not the determining factor for the grade in question.

| Trade Name | Total C, percent | Si, percent | S, percent | P, percent | Mn, percent |
|---|---|---|---|---|---|
| No. 1 soft | 3.00 ± | **2.75 to 3.25** | **0.05 and under** | 0.30 to 1.50 | 0.10 to 1.00 |
| No. 1 foundry | 3.25 ± | **2.25 to 2.75** | **0.05 and under** | 0.30 to 1.50 | 0.10 to 1.00 |

| Malleable Bessemer | 3.50 ± | 0.75 to 2.00 | Under 0.07 | Under 0.20 | 0.50 ± |
| Ferrosilicon* | 0.50 to 2.00 | **10.00 to 50.00** | Under 0.04 | Under 0.10 | 0.20 ± |
| Silicospiegel | 1.00 ± | **5.00 to 15.00** | Under 0.02 | Under 0.10 | **15.00 to 25.00** |
| Ferromanganese | 6.00 to 7.00 | 0.50 to 1.00 | Under 0.03 | .......... | **40.00 to 80.00** |
| Ferrophosphorus | 1.00 ± | 1.50 ± | Under 0.05 | **10.00 to 25.00** | .......... |
| Spiegeleisen | 4.50 to 6.00 | 1.00 ± | Under 0.04 | .......... | **15.00 to 35.00** |

* Ferrosilicon of 10 percent grade, ferromanganese, silicospiegel, and spiegeleisen are made in blast furnaces, by variations of the usual practice and by using special ores. Ferrosilicon of 30 to 80 percent grades, and several other so-called *ferroalloys*, are made in electric furnaces. These include ferrochrome, ferrotungsten, ferromolybdenum, ferrotitanium, ferrovanadium, etc. They are all practically pig irons with large amounts of the alloying metal. When these alloys are free from, or low in, carbon, they are made by the thermit and other processes.

with certain proportions of scrap, in the cupola. The various grades of pig iron and scrap are combined in the cupola charges to give the desired chemical composition of the iron in the castings. For methods of mixing and charging, see p. 20–10. The composition of the iron in the castings also may be varied by the addition of ferroalloys, as ferrosilicon, ferromanganese, etc., to the molten iron in the ladle. Soda ash and calcium silicide also may be added to the iron in the ladle to reduce the sulphur and oxygen in the metal.

**EFFECT OF VARIOUS ELEMENTS ON CAST IRON.**—**Carbon** depends on the presence of other elements. High manganese content may permit a carbon content of 7%, while high silicon may reduce carbon to 1%. Carbon may be present either in the combined form or as free graphitic carbon. Maximum tensile strength is attained when combined carbon is about 0.47%. Maximum transverse strength requires about 0.70% combined carbon, and maximum crushing strength requires over 1%. Hardness increases with the increase in combined carbon.

**Silicon** directly affects the combined carbon in cast iron. Carbon exists principally as graphite when the silicon content ranges from 0.75–2.50%. With silicon in excess of about 3.0%, its effect on the formation of graphite decreases, and when silicon increases to 4 or 5% the iron tends to become white.

**Sulphur** acts in the opposite manner to silicon, but with much greater effect. A sulphur content of 0.01% will counteract the effect of 1.15% silicon in producing graphite. Sulphur causes segregation and red shortness, and should be kept below 0.5%.

**Phosphorus** increases the fusibility, fluidity and brittleness of cast iron. It decreases shrinkage and density. Ornamental castings which must reproduce sharp impressions may contain as much as 1.5% phosphorus.

**Manganese** lessens the bad effect of sulphur, and should be present in quantities twice as great as the quantity of sulphur. It tends to make cast iron harder and more brittle. It also tends to strengthen the casting and fine the grain. It is introduced into the iron by additions of spiegeleisen or ferromanganese in the ladle.

**Nickel, Chromium, Molybdenum** are added to cast iron to increase the tensile strength. The proportions used have ranged up to 1.50% nickel, 0.50% chromium, or 0.50–1.50% molybdenum. Tensile strength of cast iron containing these elements may range as high as 70,000 lb. per sq. in.

**PHYSICAL PROPERTIES OF CAST IRON.**—Detailed specifications for gray iron castings and a discussion of the physical, electrical and thermal properties of cast iron are given in the section on Foundry Practice. See p. 20–03.

## 3. WROUGHT IRON

Wrought iron is commercial iron mechanically mixed with slag. It is the product of the reverberatory furnace or of the charcoal hearth. It melts at white heat, but is pasty at lower temperatures, and in this condition can be readily worked and welded. It is ductile when cold.

**GRADES.**—Wrought iron may be graded as: 1. Charcoal iron. 2. Puddle iron. 3. Busheled scrap. The first is the purest grade of wrought iron. The second is classified as staybolt iron (grade A) and merchant iron (grades B and C). The third grade is made from iron scrap, with which steel sometimes is mixed. It is irregular in quality.

**PROPERTIES OF WROUGHT IRON.**—Wrought iron is tough, ductile, and malleable. It can be welded readily. Its properties are only slightly changed by heat treatment. The following physical properties are given by different authorities. Specific gravity, 7.4–7.9; specific heat, 0.1138; melting point, 2732–2912° F.; coefficient of thermal expansion, 0.000 006 48; ultimate tensile strength, average 51,000 lb. per sq. in.; yield point, average, 31,000 lb. per sq. in.; elongation in 8 in., 25–40%; reduction in area, 40 55%; modulus of elasticity, 28,200,000; ultimate strength in single shear, 42,000 lb. per sq. in.; elastic limit in torsion, 20,500 lb. per sq. in.; modulus of elasticity in torsion, 12,800,000.

The ultimate compressive strength of good wrought iron is not well defined. The yield point in compression, which is about the same as the yield point in tension, should be taken as the ultimate compressive strength, for all practical purposes. The yield point ranges from 2000 to 4000 lb. per sq. in. higher than the elastic limit.

**SPECIFICATIONS FOR WROUGHT IRON.**—The Am. Soc. for Testing Materials has issued standard specifications for wrought-iron plate and bars. These are abstracted below from the 1936 Tentative* Standards.

**Wrought-iron Plates** (A.S.T.M. Designation A42–36T).—Plates shall be rolled from blooms, piles or slabs free from iron scrap or steel. Piles for plates are to be made of wrought iron. The chemical specification is Mn, max., 0.06%. Physical properties specified are: Tensile strength, min., 48,000 lb. per sq. in.; yield point, minimum, 27,000 lb. per sq. in.; elongation in 8 in., 14%. The tension test specimen should be made in the form shown in Fig. 2 (see p. 7–54), and be of full thickness of the plate as rolled, except that for plates 1 $^1/_2$ in. or more thick, specimen may be machined to a minimum thickness or diameter of $^3/_4$ in. for a distance of at least 9 in.

---

* A Tentative Standard is subject to yearly revision. The latest issue of the A.S.T.M. Standards should be consulted.

The bend test consists in bending a specimen cold through 90° around a pin, without cracking on the outside of the bent portion. Diameter of pin = (40 $t$/specified longitudinal elongation in 8 in.), where $t$ = thickness of plate, in.

A nick test shall be made. The specimen when nicked on one side and broken shall show a wholly fibrous fracture.

In *Special Forming Plate* the longitudinal strength and ductility are related directly to the transverse properties and are scaled downward in ratio to the increase in transverse properties as follows:

$$\text{Tensile strength} = 51{,}000 - (1500\ \text{T.D.})$$

Longitudinal elongation in 8 in. = 16 − T.D., where T.D. = transverse ductility of plate expressed as a percentage of elongation in 8 in. Yield point = 27,000 lb. per sq. in. Representative requirements for special forming plates in accordance with the above formulas are

| | | | | | | |
|---|---|---|---|---|---|---|
| Transverse ductility, % | 3 | 4 | 5 | 6 | 7 | 8 |
| Minimum tensile strength (longitudinal), lb. per sq. in.* | 46,500 | 45,000 | 43,500 | 42,000 | 40,500 | 39,000 |
| Elongation in 8 in., %† | 13 | 12 | 11 | 10 | 9 | 8 |

Permissible variation in weight of plates ordered to weight per sq. ft. shall not exceed the percentages given in Table 7, p. 2–28. If ordered by thickness, the thickness shall not vary by more than 0.01 in. under that ordered. The overweight of each lot in each shipment shall not exceed the amount given in Table 7, p. 2–28.

**Wrought-iron Bars, Single and Double Refined** (A.S.T.M. Designation A189–36T).—Bars shall be made from pig-puddled or processed wrought iron, free from any admixture of steel, in two grades, as follows: Grade A, original muck bars twice piled and rerolled; Grade B, original muck bars piled and rerolled. Manganese shall not exceed 0.06%. Physical properties are given in Table 2.

The cold bend test comprises bending cold around a pin through 180 deg. without showing cracks on the outside of the bent portion. The diameter of the pin shall be equal to the thickness of the specimen. The hot bend test consists in bending the specimen flat on itself at a temperature of 1700–1800° F. without showing cracks on the outside of the bent portion. The nick test comprises nicking the bar 25% around its circumference with a tool having a 60-deg. edge, to a depth of not less than 16% of the diameter or thickness of the bar, and breaking the bar slowly. The fracture should be wholly fibrous in appearance.

Tension test specimens shall be the full section of the material as rolled, if possible, or

---

* For plates over $^3/_4$ in. thick, a deduction of 1000 lb. per sq. in. from the indicated tensile strength is allowed for each increase of $^1/_8$ in. thickness over $^3/_4$ in., with a proportional reduction for fractional parts of $^1/_8$ in., to a minimum tensile strength of 39,000 lb. per sq. in.

† For plates under $^7/_{16}$ in. thick, deduct 1% from the percentage of elongation for each decrease of $^1/_{16}$ in. below $^7/_{16}$ in. thick, to a minimum of 8%.

**Table 2.—Physical Properties of Wrought-iron Bars**

A.S.T.M. Designation A189–36T

| Property | Grade A, Double-refined Bars | | | Grade B, Single-refined Bars | | |
|---|---|---|---|---|---|---|
| | Rounds, Squares or Hexagons Up to 1 $^5/_8$ in. diam.* or thick | Rounds, Squares or Hexagons 1 $^5/_8$–2 $^1/_2$ in. diam.* or thick | All Flats, Rounds, Squares or Hexagons 2 $^1/_2$ in. and over, diam.* or thick | Rounds, Squares or Hexagons Up to 1 $^5/_8$ in. diam.* or thick | Rounds, Squares or Hexagons 1 $^5/_8$–2 $^1/_2$ in. diam.* or thick | All Flats, Rounds, Squares or Hexagons 2 $^1/_2$ in. and over, diam.* or thick |
| Tensile strength, 1000 lb. per sq. in. | 48–54 | 47–54 | 46–54 | 48 | 47 | 46 |
| Yield point, min., 1000 lb. per sq. in. | 0.6× Ten. Str. | 0.55× Ten. Str. | 0.5× Ten. Str. | 0.6× Ten. Str. | 0.55× Ten. Str. | 0.50× Ten. Str. |
| Elongation in 8 in., min., percent | 28 | 25 | 22 | 25 | 22 | 20 |
| Reduction of area, min., percent | 45 | 40 | 35 | 40 | 35 | 30 |

* Short diameter of hexagons.

otherwise taken from the material as rolled. For bars 2 1/2 in. or less in diameter or thickness, the axis of the specimen shall coincide with the axis of the bar. For bars over 2 1/2 in. diameter or thickness, the axis shall be located at any point one-half the distance from the surface to the center of the bar, and parallel to the axis of the bar. It may be machined to a diameter of 1 in. for a distance of at least 9 in., with enlarged ends.

The bend test specimen for round, square or hexagon bars of not over 1 1/2 in. diameter or thickness, and flats not over 1 in. thick or 2 in. wide shall be the full section of the bar as rolled. For larger bars the specimen may be reduced to 1 1/2 in. diameter or thickness. For flats it may be reduced to a width not less than the thickness of the bar. Corners of machined edges may be rounded to a radius of not over 1/16 in.

The etch test comprises etching a ground or polished cross-section of the test specimen in a solution of 10% HCl (sp. gr. 1.19), 30% $H_2SO_4$ (sp. gr., 1.84) and 60% water, or in a solution of 25% $HNO_3$ (sp. gr. 1.42) and 75% water, for a period long enough to develop the structure and to show freedom from steel.

The step test, applicable to Grade A bars only, comprises reducing the specimen to 50% of its original diameter by smooth turned steps, each 2 in. long and 1/8 in. less in diameter than the preceding step. The specimen shall show freedom from injurious seams, laminations and other defects.

The number of tests required is as follows: Bend, tension, nick and step tests, two each, made on bars selected at random from each lot of 100 bars; etch test, one, made from the two bars selected for the other tests.

Permissible variations in size of rounds, squares and hexagons are as follows:

| Nominal size, in. . | up to 1/2 incl. | 1/2–1 incl. | 1–2 incl. | 2–3 incl. | 3–5 incl. | 5–8 incl. |
|---|---|---|---|---|---|---|
| Variation under. . . | 0.007 | 0.10 | 1/64 | 1/32 | 1/32 | 1/16 |
| Variation over. . . . | 0.007 | 0.10 | 1/32 | 3/64 | 3/32 | 1/8 |

## 4. ELECTROLYTIC AND INGOT IRON

Iron in which iron content is not less than 99.9% is tough, ductile, highly resistant to corrosion and has high magnetic and electrical properties. It is made by two processes, *viz.*, extensive refinement in the open-hearth furnace, the product being known as ingot iron; by electro-deposition, the product being known as electrolytic iron.

**ELECTROLYTIC IRON** is made from anodes of ingot iron, soft steel or pig iron. The cathodes are rotating mandrels or moving plates. The electrolyte usually is ferrous chloride. The current density ranges from 12 to 75 amperes per sq. ft. and the voltage drop is 3 to 4 volts per cell. Electrolytic iron has been used where high magnetic properties were required, but the development of alloys of high permeability has displaced it from this field.

**ARMCO INGOT IRON** * is a trade name for commercially pure iron produced by the basic open-hearth process. The operation of the furnace is similar to that for making mild steel, but the refining operations are carried farther. The reduction of metalloids to low values is accomplished by adding iron ore to the bath, which furnishes the oxygen necessary to oxidize the manganese, silicon, phosphorus, and carbon. The highly basic slag reacts with the products of oxidation to effect their removal from the bath. As the metalloids are removed during the refining period, the melting point of the metal is raised, necessitating furnace operation at a higher temperature than ordinarily used for the production of mild steel.

A typical chemical analysis of this material is: Carbon, 0.015%; manganese, 0.020; phosphorus, 0.005; sulphur, 0.025; silicon, trace.

The microstructure of Armco ingot iron consists of a simple network of grain boundaries, characteristic of all pure metals. No other phases are present than the ferrite which makes up the structure of the grains. The size and shape of the grains will differ with various mechanical and thermal treatments.

**Physical Properties.**—The average physical properties are: Specific gravity, 7.866; weight, lb. per cu. ft., 490; specific heat at 25° C., 0.108; heat of fusion, 65 calories per gram; thermal conductivity, 0.16 calorie per sec. per sq. cm. per deg. C. per cm. at 100° C.; thermal coefficient of expansion, 12.6 millionths per deg. C. (20–300° C.); electrical resistivity, 9.6 microhm-cm. at 0° C.; temperature coefficient of electrical resistivity, 0.0056 per deg. C. (0–100° C.).

Magnetic properties are best illustrated by the curves in Figs. 1 and 2. Permeability is high, and retentivity low, which make this material suitable for many special applications.

**Mechanical Properties.**—The average mechanical properties after various treatments are shown in Table 3. Young's modulus is 29,300,000 lb. per sq. in. in both tension and compression, and the shear modulus is 11,800,000 lb. per sq. in. Poisson's ratio is generally considered to lie between $^1/_4$ and $^1/_3$ for most metals, and is given for iron as 0.28 in various sources.

---

**Effect of Temperature on Mechanical Properties.**—The effect of temperature on the tensile properties as determined by short-time tests is shown in Table 4. The tensile properties at elevated temperatures are greatly influenced by the effect of creep, and the time factor must, therefore, be taken into consideration in designing structures exposed to elevated temperatures. Tapsell and Clenshaw have determined the limiting creep stress of Armco ingot iron as shown in Fig. 3.

The variation in torsional properties and the endurance limit, both at elevated temperatures, are shown in Table 5. Endurance limit, as shown, was determined on the Haigh alternating stress machine at 2400 cycles per minute with equal plus and minus stress on the basis of 10,000,000 reversals.

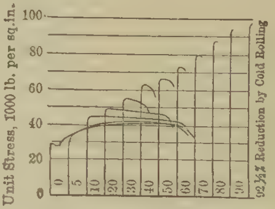

Fig. 4. Effect of Cold Rolling on Shape of Stress-Strain Curve of Armco Ingot Iron

**Uses.**—Armco ingot iron was originally developed as an especially durable metal highly resistant to corrosion, and in sheet form it has been galvanized for roofing, siding, tanks, and signs. In the corrugated form it has been used for culverts. Its high purity and freedom from gas-forming metalloids make it suitable for oxyacetylene and electric arc welding, both as material to be welded and as welding rods. It is also very suitable in the form of sheets for vitreous enameling, because of its freedom from enamel defects such as bubbles and blisters. It is very ductile, and is used for the most severe deep-drawing operations such as refrigerator parts, washing machine tubs, etc. Superior drawing properties and enameling quality are thus incorporated in a single material. Its relatively low electrical resistance, compared to steel, has led to its use as telegraph wire and bond wire for rail signal circuits for railroads. Its high magnetic permeability and low retentivity has stimulated its use for solenoid plungers, magnetic cores, and other parts of electrical equipment.

**FORMS.**—Armco ingot iron is available in the form of hot and cold rolled sheet and strip in all variations of surface and temper, in plate, wire, rods, bars, tubing, and spiral welded pipe.

**FABRICATION.—Cold Working.**—Because of its high ductility, Armco ingot iron can be bent and formed more easily than steel, thus making it possible, in some cases, to substitute cold-forming operations for hot forming with steel. Deep-drawing operations of a wide variety of forms and degrees of intricacy are carried out in cold stamping presses. It is very suitable for cold spinning operations.

**Hot Working.**—Armco ingot iron is not workable in the temperature range from 1552° to 1922° F. This is due to the very low manganese content. This temperature range is avoided in all hot-rolling and forging operations. When Armco ingot iron is to be forged or hammer welded, it should be heated to a white heat or above, when it can be worked until the temperature drops to 1922° F., or to a bright orange color. If more working is required, reheating is necessary. If worked in the critical range between the temperatures given, it will check or break. It is also possible to work the material below the lower limit of this range if hammer welding is not involved, and often this is more satisfactory than working above the critical range, because of the difficulty of preventing some portions of the piece from cooling into the critical range. When worked at temperatures either above or below the critical range satisfactory results will be obtained.

Fig. 5. Recommended Tool Shapes for Machining Ingot Iron

**Machining.**—The high ductility and extreme toughness of Armco ingot iron make it necessary to alter slightly the cutting angles of machine tools in order to get the best results. Shaper tools having a little more rake do away with the tendency to drag and will give surfaces comparable to mild steel. In the case of drilling, the clearance angle of the drill should be increased slightly, and the drill should be ground to cut continuous spirals rather than chips. Fig. 5 shows cutting angles for lathe and shaper tools and drills that have been found satisfactory.

**Welding.**—Both plates and welding wire of Armco ingot iron possess excellent welding characteristics because of purity, uniformity of grain structure, and freedom from gas-forming impurities, all of which result in a freedom from blowholes.

**Brazing and Soldering.**—The usual procedure for brazing and soldering may be carried out without difficulty on Armco ingot iron.

**Annealing.**—Annealing results in a change in the grain structure and physical properties of the material. At temperatures below the $A_3$ thermal critical point (1650° F. for Armco ingot iron), the recrystallization of the grain structure and the change in properties that is produced depends on the amount of previous cold work to which the material has been subjected. Under certain combinations of degree of cold working and annealing temperature, excessive grain growth and inferior physical properties may result. This is also true of low carbon steels, as well as Armco ingot iron, and should be borne in mind when parts are shop annealed in process of fabrication. For example, the best efforts of the manufacturer to produce a good microstructure and physical properties for deep-drawing operations will be entirely destroyed by ill-advised annealing which causes excessive grain growth after cold working. These difficulties can be largely overcome by normalizing or annealing above the $A_3$ temperature. In many cases the high degree of ductility of Armco ingot iron makes it possible to draw the finished part in one operation, thus obviating the necessity of any intermediate annealing treatment at all.

**Riveting.**—Due to the great ductility, rivets of Armco ingot iron up to $^3/_8$ in. can be driven cold. For larger sizes or whenever it is necessary to drive them hot, care should be taken not to heat them above the lower range of critical working temperature.

## 5. STEEL

Steel is iron containing up to 1.7% carbon and not containing admixed slag. The properties of steel are varied over a wide range by variations in the carbon content and in the percentage of other metals alloyed with it. These are discussed in great detail in the following pages.

**CLASSIFICATION OF STEEL.**—Steel may be classified, among other methods, by the process of manufacture, as follows:

**Bessemer Steel** is made in a Bessemer converter from melted pig iron. Only acid Bessemer steel, *i.e.*, steel made in a converter lined with silicious material, is made in the U. S. After all the constituents of the bath of iron in the converter, excepting the iron, have been burned out by means of air blown through the bath, spiegeleisen or ferromanganese is added to the bath to deoxidize the iron and give it the desired carbon content.

Bessemer steel usually is poured into ingots which are rolled into various shapes, as pipe, tin plate, etc., and drawn into wire. It also is used for the manufacture of steel castings, the converters being of about two tons capacity. In these converters air usually is blown on the top surface of the bath instead of through it, resulting in a much hotter metal, since the carbon is burned to $CO_2$ instead of to CO, as occurs when the air is blown through the bath.

**Open-hearth Steel** is steel made in the open-hearth furnace. The charge to the furnace may range from 100% steel scrap with no pig iron to 100% pig iron with no scrap, or any combination in between these limits. Liquid pig iron also may be charged to the furnace. The bath is kept liquid to the utmost limit of purification. The silicon, manganese, phosphorus and carbon are oxidized from the steel as desired, and the chemical composition is adjusted by means of suitable additions of carbon, manganese and silicon, and in the case of alloy steels by the addition of nickel, chromium, vanadium, tungsten, etc. Open-hearth steel may be either acid or basic steel, the distinction being in the character of the lining of the furnace, which, in turn, determines the character of the slag utilized in the process. In the acid open-hearth furnace, the slag is an acid slag, *i.e.*, rich in silica. Phosphorus will be repelled by such a slag and hence cannot be removed from the bath. Raw materials, low in phosphorus, must be used to obtain a good quality of steel in the acid furnace.

Basic open-hearth steel is made with a slag rich in bases, *e.g.*, lime, which will absorb the oxides of silicon, manganese and phosphorus and therefore keep them away from the steel as they are oxidized. Basic steel is free from phosphorus but may contain more oxide of iron than acid steel. Acid steel generally is preferred for service under fatigue conditions, but basic steel represents 85% of the steel used in the U. S. (1937).

**Duplex Steel** is steel that is made by the so-called duplex process in which melted metal from a Bessemer converter is used in the charge for the open-hearth furnace. The acid Bessemer process removes silicon, manganese and carbon rapidly from pig iron. If this purified metal then is charged to a basic open-hearth furnace, the phosphorus and the sulphur are removed. The duplex process produces steel in a minimum of time as compared with the other processes, except the Bessemer.

**Electric Furnace Steel** is steel made either in an arc or resistance type of furnace. The resistance type of furnace generates, by induction, electric current in the steel bath which is heated by virtue of the resistance of the steel to the passage of current through the bath. In the electric arc furnace, which is similar in operation and design to fuel-fired furnaces, the arc, instead of a flame, heats the charge. It is, therefore, capable of much higher heats than either the open-hearth or Bessemer furnace. Its distinguishing characteristic, however, is the absence of an oxidizing or carbonizing flame, enabling iron or steel scrap to be melted without either oxidizing or carbonizing. The electric furnace thus offers the advantage of a furnace atmosphere that may be neutral or reducing as desired, since the charge does not come in contact with any products of combustion. It also is possible to maintain a slag quite free from iron oxide. Such a slag will purify steel to any desired limit by eliminating sulphur, oxygen and oxide. Only the basic electric furnace can hold this purifying slag, but the acid furnace can remove all impurities except phosphorus and sulphur. The basic electric arc furnace hence is used largely for super-refining, that is, for the final stages of desulphurization and deoxidation of steel from the basic open-hearth furnace. The electric furnace has largely supplanted the crucible furnace for making tool steels and alloy steels for high-speed cutting tools.

**Crucible Steel** is steel made in pots or crucibles holding about 100 lb. of metal, and heated, usually, in a pit furnace. The raw material consisting of wrought iron, steel scrap or pure cast iron is packed in the crucible with charcoal or carbon, melted, and held at furnace heat for about one-half hour. Manganese is added to remove oxide from the iron, and silicon is absorbed from the crucible together with carbon, if the crucible is made of graphite. The quality of crucible steel depends on its freedom from objectionable elements as phosphorus, and on the complete removal of oxides, slag and blowholes. This is accomplished by dead melting or killing before pouring, and on the proper addition of alloying elements, as carbon, manganese, chromium, tungsten, etc. While the crucible process was the principal source of tool steel for nearly 150 years, it is now (1937) relatively unimportant.

**IDENTIFICATION OF DIFFERENT TYPES OF STEEL.—Acid and Basic Steel.***—Acid open-hearth or Bessemer steel may be distinguished from basic steel by being lower in manganese, sonims,† and oxygen, but higher in silicon, phosphorus and sulphur. It dissolves more slowly in dilute sulphuric and hydrochloric acids than does basic steel.

**Basic Open-hearth and Acid Bessemer Steel.**—Manganese, silicon, phosphorus and sulphur will be lower, and sonims† and oxygen higher in basic open-hearth than in acid Bessemer or acid open-hearth steel. Basic open-hearth steel dissolves more rapidly than acid Bessemer steel in dilute acids. For the same tensile strength, basic open-hearth steel will be more ductile than acid Bessemer steel with the possible exception of some steel castings.

**Acid Open-hearth and Acid or Basic Bessemer Steel.**—Acid open-hearth steel will have fewer sonims, less oxygen and manganese than acid or basic Bessemer steel, and less phosphorus than acid Bessemer steel.

**Crucible Steel** normally has less than 0.4% manganese, and more than 0.2% silicon, while open-hearth and Bessemer steels have more manganese and less silicon than these figures, except that silicon in steel castings may be higher. Crucible steel usually is high in carbon. If steel with not more than 0.30% carbon is sold as crucible steel, it should be tested for sonims which should be less than 0.03%. As yet (1937) there is no definite means for distinguishing crucible from electric steels except in the low carbon grades. In these grades, silicon usually is over 0.20% in crucible steel, and under 0.20% in electric steel.

**Electric Steel** usually runs under 0.40% manganese and under 0.50% silicon (except in steel of over 0.60% carbon). Even with high carbon steel, except steel castings, silicon generally is under 0.20%. Sonims practically are absent in best quality electric steel. Electric steel has higher elongation and reduction of area for the same tensile strength than any steel except crucible steel. It dissolves much more slowly in dilute sulphuric and hydrochloric acids than does basic open-hearth steel, which alone equals it in low phosphorus.

**EFFECT OF INGREDIENTS ON PROPERTIES OF STEEL.**—The effects of the various elements on the properties of steel are listed below.

**Carbon.**—The effect of carbon on steel is to some extent modified by the effect of other elements, and by the heat treatment that the steel may receive. In general, however, increase of carbon tends to decrease the specific gravity, melting point, elongation, reduction of area and modulus of elasticity, and to increase the tensile strength, yield point, and hardness. The hardness and cutting power of quenched and tempered steels varies almost directly with the carbon from 0 to 2%, the common commercial limits. Above the point of 100% pearlite, *i.e.*, 0.85% C, the cutting power increases more rapidly because of the cementite embedded in the mass. Softness, malleability and toughness decrease in proportion as hardness and brittleness increase with increasing carbon. See Tables 18 and 19 for the effect of various percentages of carbon and various heat treatments on different grades of steel.

**Manganese** increases strength and hardness, decreases oxygen content and mitigates the effect of oxygen and sulphur in the steel.

**Phosphorus** increases strength, brittleness, segregation and fluidity and decreases resistance to shock. With normal heating, it increases grain size.

**Sulphur** slightly increases strength but makes steel dirty, oxidized, segregated, brittle under shock, and red-short. The effect of sulphur can be lessened by the presence of twice the quantity of manganese.

---

* This does not include acid and basic electric steel.

† Sonims are the solid non-metallic impurities in iron and steel, including slag particles, sulphides of iron or manganese, oxides of iron, silicon, aluminum, etc., or dirt from ladle or furnace linings.

**Copper** increases hardness of steel. In quantities of less than 1% it will decrease the tendency to corrosion. See Atmospheric Corrosion, p. 3–06. It appears to decrease segregation and grain size.

**Silicon** increases strength and hardness and decreases ductility. It increases the solvent power of steel for gases, especially oxygen and carbon monoxide. This influence decreases blowholes in soft steel, but increases the volume of pipe in ingots and castings. Silicon increases grain size. In castings, 0.20 to 0.40% of silicon often is added for the purpose of increasing strength. Silicon is used in cores of electro-magnets to increase electrical resistance and, therefore, diminish eddy currents.

**Oxygen** may occur in steel as $CO$, $FeO$ or $Fe_2O_3$, being harmful in any of the three forms. Its action is similar to that of sulphur. It produces brittleness in both hot and cold steel, and promotes the formation of blowholes. It probably is the most harmful of all constituents of steel. No satisfactory method has been found (1937) for rapidly determining small traces of oxygen.

**Nitrogen and Hydrogen** both occur in steel in very small quantities. Nitrogen is important in connection with arc welding, when a needle-like constituent appears, which is thought to be a crystal of iron nitride.

**Sonims** are the solid non-metallic impurities found in iron and steel. They include slag particles, sulphides of iron or manganese, oxides of iron, manganese, silicon, aluminum, etc., or dirt from ladle or furnace linings. Sonims remain suspended in some steel baths or ingots until caught in the solidifying mass. The crucible and electric processes of steel making give the best opportunity for the metal to clarify itself. Sonims in steel to a harmful extent are caused solely by bad steel-making practice, such as lack of care in adding oxidizing agents too near the end of the process, or adding deoxidizers in the ingots after the steel has become too cold to allow, for example, oxide of aluminum to rise to the surface.

## 6. METALLOGRAPHY OF IRON AND STEEL

**MICROSCOPIC CONSTITUENTS OF IRON AND STEEL.**—Iron and steel are not simple, homogeneous substances, like glass, but are composed of grains and crystals of different constituents. Thus, there may be, in slowly cooled iron castings, crystals of graphite, cementite, ferrite, and pearlite. The strongest simple steel made (excluding alloy steels, etc.) consists entirely of pearlite. Not only the kinds of constituents but also the size of the crystals in which they occur has an important effect on the qualities of the material which they compose. Thus, large crystals of graphite, etc., indicate weak and non-ductile metal. There are also other constituents which appear under the microscope, such as nitride of iron, and also minute particles of slag, oxides of iron, manganese, and silicon, sulphide of iron or manganese, carbide of manganese, etc. The following is a brief description of the principal constituents of iron and steel.

**Ferrite** is pure iron. It is soft, ductile, malleable; it can stand a great amount of cold work without annealing; it is not strong. It has a tendency to form in rather large crystals during cooling from solidification, or from a high temperature. It will not harden on rapid cooling, and can be formed of small-sized crystals if heated to a bright red heat and cooled very rapidly.

**Graphite**, which appears as free carbon in cast iron, occurs in flat plates which separate under strain. Its effect is to greatly weaken the iron. As the size of the crystals increase, the tensile strength of the iron decreases. Gray cast iron breaks along the planes of the graphite crystals. These, being the only substance visible, give the iron its characteristic color.

**Cementite** is carbide of iron, $Fe_3C$. Its hardness is 6 to 6.5 on Moh's scale, and U on the mineralogical scale. It will scratch glass, but not quartz. It is magnetic below 400° F. It decreases the tensile strength of iron and steel, but increases hardness and cutting properties.

**Pearlite** is an aggregate made of alternate crystals of ferrite and cementite. Its chief characteristic is its minute crystal size. Pearlite has about 7 parts by weight of ferrite to 1 part of cementite, and therefore contains about 0.85% carbon. Steel of this carbon is the strongest simple steel known.

**Austenite** is a solid solution of ferrite and cementite in each other. It forms when the metal solidifies, and remains a solution until it cools to a red heat. But 10% of manganese and over in the steel will preserve austenite to a temperature below 0 F., as will 12 to 25% nickel. Austenite is hard and non-magnetic; it resists wear, but is not brittle. Chromium assists rapid cooling to preserve some of the austenite. If austenite contains 1 part of cementite dissolved in 7 parts of ferrite, the solution will remain until the steel cools to a dark red heat. Precipitation then will occur and if the cooling is slow, the solid steel will change over into a pearlite structure. If the austenite contains more ferrite than the above proportions, ferrite crystals will begin to separate out progressively as the steel cools below a bright red heat, until a dark red heat and a proportion of ferrite to cementite of 7 to 1 is reached at one and the same time. Further cooling causes precipitation of this remaining austenite, and the final steel at atmospheric temperature contains ferrite crystals in pearlite. If the cementite be greater in proportion than 1 to 7, it will begin to separate crystals at bright red heat, with the same procedure, except that the cold steel will contain cementite crystals in pearlite.

**Martensite** is the chief constituent of rapidly-cooled steel. It is the imperfectly preserved austenite, which could not be cooled rapidly enough to prevent some decomposition, but was not so slowly cooled, as to precipitate into pearlite with or without some ferrite or cementite. It is a common constituent of hardened steels. It is not as tough as austenite, but is tough and brittle. It also differs from austenite in being magnetic, but is not as much so as is the same steel slowly cooled.

**Troostite** is a stage in the transformation of austenite one step beyond martensite; it also may be called a stage in the transformation of martensite. It may be formed in any one of three ways: 1. Cool rapidly to produce martensite; then temper to produce troostite. 2. Cool with moderate rapidity, such as quenching in oil. 3. Cool slowly until the transformation begins; then cool rapidly to prevent its completion. Troostite has somewhat less hardness and less brittleness than martensite.

**Sorbite** is the next step beyond martensite in the transformation. It is almost pearlite, and is desirable because of its strength. It has some of the durability of fully precipitated steel. It is formed by the cooling of steel, at a moderately rapid rate, from the temperature of solid solution to atmospheric temperature.

Fig. 6, p. 2–17, shows the relations between the various constituents of steel and iron at various temperatures and carbon contents.

For a discussion of the metallography of iron and steel, see Eshbach, Handbook of Engineering Fundamentals, pp. 11–26 to 11–29, forming Vol. 1 of this series.

## 7. HARDENING, ANNEALING AND TEMPERING

**HARDENING OF STEEL.**—The normal practice in hardening simple steel consists in heating it above a dark red heat and cooling it rapidly, as by plunging it in water, iced brine, or other liquid. The rationale of this is that the steel is heated above the line *PS* in Fig. 6, and cooled rapidly with the expectation of suppressing the change which would occur in slow cooling, that is, the change from austenite to pearlite, etc. What actually occurs is the transformation of the steel into martensite (see p. 2–17) which is hard and brittle. The rapid cooling along the line *PS* sets up strains in the metal, which sometimes are so great that the steel flies into pieces during hardening.

**Rationale of Hardening and Annealing.**—The *critical point curves* in Fig. 6 form the scientific basis of heat treatment. When iron or steel is heated above the line *PSK*, austenite forms; if it is heated within the area *AGOSE*, then all the steel is austenitic, that is, all the ferrite, or cementite (or carbon) is dissolved in the austenite. If now the austenite be formed and cooled rapidly, there is retained in the material some of the imperfectly transformed austenite, that is, martensite, or troostite. The hardness is due to these constituents. If, on the other hand, after forming austenite by heating above the line *PSK*, the steel be cooled slowly, the austenite will break up into pearlite. The softness and ductility of annealed steel is due to pearlite with ferrite.

The hardness of quenched steel usually is believed to be due chiefly to the hardness of the martensite. Martensite is believed to be composed of crystals of iron, body-centered tetragonal, or body-centered cubic, holding carbon in solid solution. Therefore, it must be a highly saturated solution in the high-carbon steels that usually are quenched. The hardness of martensite is believed to be due to the extremely small grain size. It also is believed that the austenite, during its rapid cooling, has broken down into at least incipient crystals of $Fe_3C$, which are distributed throughout the mass in a sub-microscopic size in a state of what is called *critical dispersion.* These extremely small hard crystals of $Fe_3C$ interfere with slip or movement within the crystals, and are responsible for the hardness of the mass.

**Temperature of Breaking Down of Austenite.**—When austenite is quenched, it is believed that it decomposes, not at 1300° F. as normally occurs according to the change phases shown in Fig. 6, but that the change point is depressed to about 500° F. at which temperature there is partial precipitation of $Fe_3C$ in extremely small size. Steel to be properly quenched must be cooled at a rate known as the *critical cooling velocity.* This is the speed of cooling which will prevent any change in the austenite until a temperature of about 500° F. is reached, and yet not so rapidly that some of the austenite will remain unchanged to martensite.

**Correct Temperature for Hardening.**—If steel is heated far above the line *PSK* its crystals grow to large size, which causes weakness and "shortness." (Shortness is that type of brittleness displayed by gray cast iron when it breaks, as distinguished from the violent, springy breaking of strong, hard tool steel.) The fracture shows to the eye bright crystal faces, and is described as "crystalline" or "fiery." Under the microscope the crystals are large, as compared with the minute size of grain of steel that is "silky" or "sappy." A test piece of overheated steel has a straight fracture as compared with the cup-and-cone fracture of "silky" steel, which is associated with high quality steel of low carbon and small crystal size. All heating of steel for quenching, whether of low or high carbon, should stop at the temperature where the steel loses its magnetism.

**Restoring Overheated Steel.**—Overheated steel may be restored to a fine size crystal, called refining, by allowing it to cool to below red heat and then reheating it to 1350° F. If the steel has not remained too long at the high temperature its structure may be wholly refined by one reheating. In this respect it differs from "burnt" steel which cannot be restored to good quality by any number of reheatings, unaccompanied by forging or rolling.

**Use of Pyrometers.**—In all careful heating, whether for hardening or annealing, the best practice controls the temperatures by means of pyrometers. Good quality will be promoted if each new kind of steel is studied experimentally to determine the best temperature, *i.e.*, the temperature that gives the best crystalline structure, irrespective of hardness. The hardness should be controlled by the chemical analysis and not by varying the temperature of hardening. This, of course, does not apply in tempering.

In automatically controlled heat-treating furnaces control is exercised both by pyrometers and magnetic indicators.

**RATIONALE OF GRAIN REFINING.**—When the austenite is formed, the recrystallization due to the dissolving of the constituents in one another has a tendency to destroy the previous crystals. A minute grain structure results at the temperature where the solid solution forms on heating. This structure increases in crystal size in proportion to the temperature above its formation point. If the steel be heated up near the line *AE* the structure becomes very coarse, and the crystals do *not* break up as the temperature falls. They either must be broken up by rolling or forging down to the temperature where they are normally small, or the metal must be allowed to cool below the line *PSK*, and then reheated to the point where the grain will be small. But if the excessive heating has been to a very high temperature, or maintained a very long time at the elevated temperature, then a mere reheating over the line *PSK* may not be effective in entirely curing the defect. The crystals either must be broken up by rolling or forging, or the steel twice reheated over the line *PSK*. It is most effective to first reheat to a moderately excessive temperature; this breaks up the very coarse crystals, but leaves them still coarser than they should be. A second reheating to exactly the right point restores to the steel the best structure obtainable by heat treatment alone. Rolling or forging below the line *PSK* makes finer crystals than does heat treatment alone, but slightly lowers the ductility. Cold rolling makes the smallest crystals of all; wire drawing is equally potential. By wire drawing to very small sizes, tensile strengths may be obtained in ordinary carbon steel (piano wire, for example) up to 400,000 lb. per sq. in., but with almost no ductility left.

**Effect of Heat on the Grain of Steel.**—A simple experiment will show the alteration produced in a high-carbon steel by different methods of hardening. If a bar of such steel be nicked at about 9 or 10 places, about $^1/_2$ in. apart, a suitable specimen is obtained for the experiment. Place one end of the bar in a good fire, so that the first nicked piece is heated to whiteness, while the rest of the bar, being out of the fire, is heated up less and less as the other end is approached. As soon as the first piece is at a good white heat, which burns a high-carbon steel, and the temperature of the rest of the bar gradually passes down to a very dull red, the metal should be taken out of the fire and suddenly plunged in cold water, where it should remain until quite cold. It should then be taken out and carefully dried. An examination with a file will show that the first piece has the greatest hardness, while the last piece is the softest, the intermediate pieces gradually passing from one condition to the other. On breaking off the pieces at each nick, it will be seen that very considerable and charactertistic changes have been produced in the appearance of the metal. The first burnt piece is open or crystalline in the fracture; the succeeding pieces become closer and closer in the grain until one piece is found to possess a perfectly even grain and velvet-like appearance. The first pieces also, which have been too much hardened, probably will be cracked; those at the other end will not be hardened through. Hence if it be desired to make the steel hard and strong, the temperature used must be high enough to harden the metal through, but not sufficient to open the grain.

**Effect of Heat Refining on Size of Crystals.**—Heat refining does not always make all the crystals small. For example, if a steel of 0.50% carbon be heated just above the line *PS K*, say to 1350° F., austenite begins to form with a very small grain size. There is, however, some ferrite which does not dissolve in the austenite, *i.e.*, the ferrite which separated from solution in cooling from the point *O* to the line *PS*. If, however, the heating is continued to higher temperatures, the ferrite progressively dissolves in the austenite, until, at the point *O*, the steel consists wholly of austenite. But in so doing, the austenite first formed has been overheated. This leads to double heat treatments. Thus, if the steel under discussion should be heated to the point *O* and cooled very rapidly, ferrite would be denied the time to separate, and the structure would be minute throughout, but the steel would be brittle from martensite. Most of the ductility then can be restored by reheating just above the line *PS* and cooling slowly.

**ANNEALING.**—The object of annealing steel is for the purpose of securing homogeneity of structure that is supposed to be impaired by unequal heating, or by the manipulation necessarily attendant on certain processes. The objects to be annealed should be heated throughout to a uniform temperature and uniformly cooled.

The physical effects of annealing, as indicated by tensile tests, depend on the grade of steel, or the amount of hardening elements associated with it; also on the temperature to which the steel is raised, and the method or rate of cooling the heated material.

The temperatures employed will vary from 1000° F. to 1500° F. In some cases the heated steel is withdrawn at full temperature from the furnace and allowed to cool in the atmosphere; in others the mass is removed from the furnace, but covered under a muffle, to lessen the free radiation; or, again, the charge is retained in the furnace, and the whole mass cooled with the furnace, and more slowly than by either of the other methods.

The best results from annealing probably will be obtained by the following procedure: 1. Introducing the material into a uniformly heated oven, in which the temperature is not so high as to cause a possibility of cracking by sudden and unequal changing of temperature. 2. Gradually raising the temperature of the material until it is uniformly about 1200° F. 3. Withdrawing the material after the temperature is somewhat reduced and cooling, under shelter of a muffle, sufficiently to prevent too free and unequal cooling on the one hand, or excessively slow cooling on the other.

**Fining the Grain by Annealing.**—Steel which is coarse-grained on account of leaving the rolls at too high a temperature may be fine-grained and have its ductility greatly increased without lowering its tensile strength by reheating to a cherry-red and cooling at once in air.

**Annealing to Relieve Strains.**—Forgings and castings of irregular shape are subject to internal strains, which may cause them to fail in service. These strains usually may be removed by heating the piece to the temperature of mobility, not necessarily to a red heat. Usually it is undesirable to heat forgings above 1300° F., as it lessens the fine structure that should have been given it by the mechanical treatment.

**Annealing of Steel Castings.**—The structure of steel castings is a feature of great importance. They do not get the beneficial kneading effect on the grain that rolled steel obtains, and the size of crystals must depend on the temperature of casting, rate of cooling, etc. When this crystal size is too large, or too open, both ductility and strength suffer. Correct annealing will improve all the qualities. The general rule is that steel castings must be reheated very slightly above the line *GOS* in Fig. 6, that is, above the temperature at which magnetism vanishes, and cooled slowly enough to acquire the requisite ductility. Research often is necessary to determine the best treatment. It must be borne in mind that it is the proper structure that is desired, and that tensile test, elongation, etc., are only indications of the structure. When the analysis is right and the mechanical qualities are not up to standard, it usually is evidence enough that the grain structure is too large; there even may be fine-sized crystals, but set in a network of large size, indicating a relict of bad crystallization when first cooled, called *ingotism*. In such case, it may be best to heat first to a high temperature; this breaks up the coarse network, but leaves the individual crystals large and "fiery." They may be refined by a second heating to immediately above the line *GOS*.

Damage to the structure of a steel casting most often is due either to too high casting temperature, or to too slow cooling just before the solidification temperature. For the very best structure, carbon steel castings of less than 0.25% carbon should be reheated to 1500° F., and then cooled rapidly to 1300° F., but for their best degree of softness and ductility, they should cool slowly from 1300° F. to 1100° F. This can best be accomplished by a double heating and cooling, when the cost thereof is justified. Specifications for annealing various classes of steel products are given in the notes accompanying Table 6.

**Annealing Tool Steel.**—Annealing or softening tool steel is accomplished by heating steel to a red heat and then cooling it very slowly, to prevent it from getting hard again.

There is nothing gained by heating a piece of steel hotter than a good, bright cherry-red; on the contrary a higher heat has several disadvantages: First, if carried too far it may leave the steel actually harder than a good red heat would leave it. Second, if a scale is raised on the steel, this scale will be harsh, granular oxide of iron, and will spoil the tools used to cut it. Third, a high scaling heat continued for a little time changes the structure of the steel, makes it brittle, liable to crack in hardening, and impossible to refine.

To anneal any piece of steel, heat it red-hot; heat it uniformly and heat it through, taking care not to let the ends and corners get too hot. As soon as it is hot, take it out of the fire, the sooner the better, and cool it as slowly as possible. A good rule for heating is to heat it at so low a red that when the piece is cold it will still show the blue gloss of the oxide that was put there by the hammer or the rolls. Steel annealed in this way will cut very soft; it will harden very hard, without cracking, and when tempered, it will be strong, nicely refined, and will hold a keen, strong edge.

**Annealing Alloy Steels.**—Special directions are necessary for annealing alloy steels used for cutting tools, etc. Such directions should be obtained from the maker. General directions will only be confusing. For nickel-steel, chromium-steel, etc., it may be assumed that slow cooling from a temperature above the critical points will soften the material. Chromium steels require specially slow cooling.

**TEMPERING.**—Tempering steel is the act of giving it, after it has been shaped, the hardness necessary for the work it has to do. This is done by first hardening the piece, generally a good deal harder than is necessary, and then toughening it by slow heating and gradual softening until it is just right for work. A piece of steel properly tempered always should be finer in grain than the bar from which it is made. If it is necessary, in order to make the piece as hard as is required, to heat it so hot that after being hardened the grain will be as coarse or coarser than the grain in the original bar, then the steel itself is of too low carbon for the desired work.

**Tempering by Oil Quenching.**—Tempering means literally "softening," and originally referred to drawing the hardness from quenched steel by reheating to temperatures of 425° F. to 625° F., as described above. Long usage, however, has caused the term among tool-makers to mean giving to steel the correct hardness for cutting purposes. Therefore, "oil tempering" relates to quenching steel in oil from a red heat. The trade now supplies oils of different degrees of cooling power, adjusted to give different degrees of hardness on quenching, and this hardness does not require any tempering. Quenching in melted lead gives less hardness than quenching in oil.

**Oil Tempering for Strength.**—The elastic limit of forgings may be raised by heating them to 1350° to 1550° F. as the case may be, and quenching them in heavy oil. Steel castings may be strengthened in this way if the shape is not such as to make them liable to crack while cooling. See notes accompanying Table 6, p. 2–22.

**DOUBLE HEAT TREATMENTS FOR STRENGTH.**—The theory outlined above is the basis of double heat treatments for increasing the strength of steels, especially steels very low in carbon, which are not much hardened by rapid cooling and whose structure is normally coarse on account of much ferrite.

## 8. ALLOY STEELS

**PROPERTIES OF CARBON STEELS WITHOUT THE SO-CALLED ALLOYING ELEMENTS.**—Normal carbon steel always contains small-sized crystals of Fe, known as ferrite, and of $Fe_3C$, known as cementite. A pure alloy containing 0.83% carbon, which corresponds to the point $S$ in the equilibrium diagram, Fig. 6, consists entirely of small-sized crystals of Fe and $Fe_3C$. With less than 0.83% carbon there are also large crystals of Fe; with more than 0.83% carbon there are also large crystals of $Fe_3C$. No normal carbon steel contains both large crystals of Fe and large crystals of $Fe_3C$.

Fe crystals are relatively soft, tough, ductile, not very strong, and yield easily along slip planes so as to be capable of considerable deformation before breaking. When relatively large areas of Fe crystals are present, as in steels of 0.22% C for example, the steel yields so easily that it breaks without exhibiting great strength, or even very great ductility. The $Fe_3C$ crystals occur in thin plates. When there are several crystals of $Fe_3C$ in excess of the small crystals of $Fe_3C$ and the small crystals of Fe, as, for example, in steel containing 1.25% C, the hard, brittle, cementite planes do not adhere strongly to the conglomerate. Steel containing 0.83% C is the strongest normal steel, because it has no large-sized crystals. This steel has a slight ductility, represented by about 5% elongation in 2 in., entirely due to the deformation which the crystals of Fe suffer under strain. This deformation is limited by the unyielding nature of the $Fe_3C$ crystals with which they are mingled in intimate contact. By *spheroidizing* the steel, the crystals of $Fe_3C$, both in the fine crystal matrix and in the excess, if any, become rounded rather than plate-like, and the toughness and resistance to impact is greater when steel is spheroidized by heat treatment than when in the unspheroidized condition.

Finally, the Fe and $Fe_3C$ are completely in solid solution above the lines *GS* and *SE* in Fig. 6. As the steel cools from these temperatures, any Fe in excess of 99.15% (for example, in steels containing 0.30% C) will begin to separate as the steel cools slowly past the line *GS*; if the carbon is in excess of 0.83 (which corresponds to $Fe_3C$ = 12.45%), any excess of $Fe_3C$ above 12.45% will begin to separate as the steel cools slowly below the line *SE*. Whatever the composition of the steel, small crystals of Fe and $Fe_3C$ completely separate from each other and eliminate any residual of solid solution left when the steel cools slowly below the line *PSK*. If, instead of cooling slowly, the rate of cooling is regulated, the breaking up of the solid solution which normally occurs in the areas *GPS* and *FCESK* in Fig. 6 can be prevented, to a greater or lesser degree.

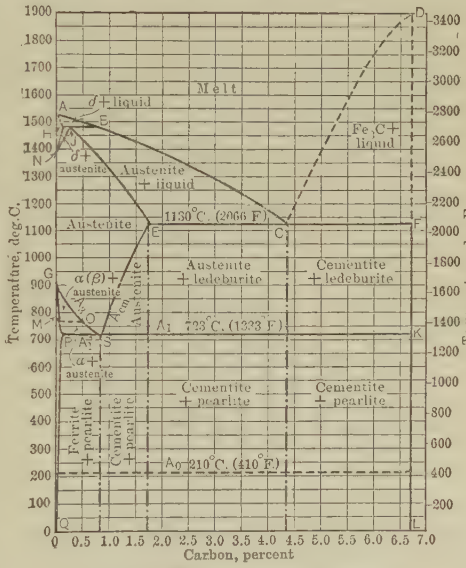

FIG. 6. Iron—Iron-carbide Diagram

**EFFECTS OF HEAT TREATMENT.**—Heat treatment of plain carbon steel will alter the size of the crystals of Fe and $Fe_3C$, or the shape of the crystals of $Fe_3C$, or the relation of these crystals to each other. Therefore, by varying the number of crystals of Fe and $Fe_3C$, which can be controlled by the amount of carbon in the steel, and by varying the heat treatment, steel may be made either hard or soft, or brittle or strong or not so strong, or high in magnetic retentivity or in permeability, or tough or ductile, etc.

**EFFECT OF ALLOYING ELEMENTS.**—Alloying elements such as nickel, chromium, vanadium, silicon, etc., will alter the phase changes, shown in Fig. 6, just as heat treatment will do, and will sometimes control them more effectively. For example, with more than 7% Mn or more than 20% Ni, or a suitable combination of two alloying elements, such as 18% Cr with 8% Ni, a solid solution can be retained down to atmospheric temperature; whereas, with heat treatment alone, the separation of the constituents can be only partially prevented, resulting often in the semi-separated, hard, brittle material which is familiar in tool steels. Alloying elements also will enter into the Fe or $Fe_3C$ crystals, as the case may be, and further alter their properties; for example, nickel will dissolve in the Fe crystals and make them harder, more rust resisting, and having greater resistance to impact stresses, especially at temperatures at and below freezing; chromium and vanadium will greatly intensify the hardness of $Fe_3C$, etc.

**NICKEL STEELS.**—Because nickel dissolves in ferrite, it is especially valuable in the low carbon steels. It causes the point *S* in Fig. 6 to move to the left, so that slowly-cooled nickeliferous steels of 0.35% C will have less excess Fe at atmospheric temperature than they would have if the nickel were not present. Furthermore, the presence of the nickel makes the Fe crystals which do come out in the area *GSP* much smaller than they otherwise would be. Therefore, a structural steel containing 0.35% C and 3.75% Ni will have almost twice the tensile strength and more than twice the elastic limit, with only about 20% less ductility, than the ordinary structural steel containing 0.22% C. The nickel steels also will have increased resistance to fatigue and to impact. Nickel steels also show greater improvement with heat treatment than do carbon steels as regards resistance to static stresses, fatigue stresses, and impact stresses. Because of the smaller size of Fe crystals, nickel steels containing 3%, 5%, and 7% Ni respectively, are used for carburizing, because the cores, which, in America, contain about 0.20% C, are tougher and stronger. In this connection a nickel-chromium steel, containing commonly 1.5% Ni and 0.65% Cr, gives very high strength after suitable heat treatment; the cores are not only tough, but the cases are extra hard because of the presence of the chromium and 0.90% carbon

(13.5% $Fe_3C$). A two-volume monograph on the alloys of iron and nickel issued by the Alloys of Iron Research Committee (McGraw-Hill Book Company, publishers) contains practically all the information extant in any language on the subject of nickel steels.

**Uses of Nickel Steels.**—Doubtless the largest use of nickel steels is for structural work, including buildings, bridges, automobiles, etc., and also rotating shafts, such as propeller shafts in vessels, which are now almost all hollow nickel steel shafts, axles in locomotives and other special purposes, airplanes, etc. Nickel also is used commonly with chromium, with molybdenum, with vanadium, or a combination of all three, and less often with manganese and other elements to form so-called *quaternary alloys*, meaning iron, carbon and two others. To a lesser extent nickel steels are used because of their hardness and because of their slightly increased resistance to corrosion. A special nickel steel containing 42% Ni and known as platinite has, at atmospheric temperature, the same expansion and contraction as glass. This alloy therefore is used for wires in the base of incandescent electric light bulbs, for armored glass, etc. An alloy containing 36% Ni is known as Invar. It has almost no expansion or contraction with atmospheric changes of temperature, and therefore is used for instruments of precision, pendulums, watch springs, surveyor's measuring tapes, etc.

**CHROMIUM STEEL.**—The best known chromium steels are the various types of stainless steel, which will be considered in a special paragraph below. Chromium makes the phase changes illustrated in Fig. 6 much more sluggish and slow to occur. It also hardens $Fe_3C$. For both of these reasons it intensifies the hardness produced by quenching steel. This is most important in increasing the depth of hardness of quenched articles and also in getting hardened materials by quenching in oil instead of water, which is less liable to produce distortion or cracking. For these purposes about 0.5% to 1.5% Cr ordinarily is used. Chromium moves the point $S$ in Fig. 6 to the left and, on quenching, produces a steel with extremely small crystals. For both these reasons it greatly increases the strength of the quenched material. Because of the very sluggish reaction which takes place in chromium steels, it is important to heat them to a higher temperature than other steels before quenching and also to " soak " for a longer time at temperature. A two-volume book on the Alloys of Iron and Chromium issued by the Alloys of Iron Research Committee contains practically all the available information on this subject to date (1937).

**Uses of Chromium Steels.**—Chromium is used in all steels where intensity or depth of hardness is to be increased, or equal hardness is to be obtained with less severe quenching. With chromium less than 1%, the steels are used largely for case hardening and structural steels for strength, especially when combined with nickel or vanadium. Steel containing between 1% and 2% Cr and from 0.75% to 1% C is used very largely for bearings, crushing machinery, burglar-proof safes, and tools. When heat treated, it has the highest combination of hardness and toughness of any plain or alloy steel. It is given a spheroidizing heat treatment before quenching. With 0.70% to 5% C (usually 2% to 4%) and 0.75% to 1.05% C, it is much used for permanent magnet steels. Heat-treated chrome-nickel steels for strength usually contain about 1.50% Ni and 0.65% Cr, or a like combination in which the nickel is approximately 2 1/2 times the chromium. The chrome-vanadium steels usually contain about 1% Cr and 0.18% V. They have a high combination of strength with toughness, and a high impact resistance.

**STAINLESS STEELS** (see also p. 3–19).—Chromium decreases the rusting of ordinary steel; when the amount of chromium is at least 11.5%, the steel retains a bright mirror-like surface in the atmosphere, whence the name stainless steel. These steels also resist the attack of many agents, such as nitric and acetic acids, fruit juices, dairy products, alkalis, oil refinery residua, etc. Especially when the chromium is above 17% or when there is a combination of 18% Cr with 8% Ni, they do not scale so readily at high temperatures as other steels. If they contain more than about 0.10% C and not more than 12% to 15% Cr, they must be heated until all the carbide is in solid solution and then quenched. Otherwise they will not resist corrosion and staining. The high strength combined with good ductility of the stainless steels also finds extensive use in the manufacture of airplanes, high-speed trains, and other purposes where strength and lightness of weight are important. The Book of Stainless Steels, edited by Ernest E. Thum (second edition, 1935), gives a wealth of information on this material and its uses.

**AUTOMOBILE ALLOY STEELS.**—The greatest tonnage of alloy steels comprises those containing nickel or chromium or both. With the exception of stainless steels, about 80% of all the alloy steels made are used in automobile manufacture, and many of these are the so-called quaternary steels, *i.e.* those containing three elements besides iron, for example, carbon, nickel, and chromium. See p. 2–37 for further details of the various automobile steels and their treatment.

**HEAT TREATMENTS FOR ALLOY STEELS.**—Even alloy steels are not so markedly increased in tensile strength when annealed in the usual manner, but the circumstance that they may be cooled with some degree of rapidity without great loss of ductility permits them to be quenched in heavy or medium oil. Thus their elastic limit and strength may be increased without destroying the toughness requisite in machinery parts. The treatment consists in raising the steel to a temperature above the line *GS* in Fig. 6, which line will be at somewhat different temperatures for different alloying elements; then soaking the steel until it is all in a solid solution, and quenching in oil; it then is drawn to temperatures of 800° to 1400° F., depending on the ductility required. Typical heat treatments are given in Table 20 and in the notes accompanying Table 6. However, every second or third year the A.S.M. publishes a new edition of the *Metals Handbook*, in which will be found the latest information as to the most desirable temperatures and treatments. The important point is that the first heating must bring the steel to a state of complete solid solution and the second heating must not be above the line *PSK* for the steel being treated.

**HIGH-SPEED STEEL.**—Tungsten and molybdenum have the apparently unique property of conferring on hardened steel the power of retaining its hardness even when heated for a few hours to 1150° F. (low red heat). Usually, hardened carbon steel will begin to soften at 200° to 300° F. Tungsten and molybdenum also give the steel some degree of self-hardening power; and, finally, they prevent the coarsening of the structure which occurs in ordinary steel when it is heated to bright red, or white, heats. Therefore a steel having 6% to 20% of tungsten, or 3% to 10% of molybdenum (or part of each), can be heated to near its melting point without damage. If then it be cooled with moderate rapidity, it will be harder than ordinary tool steel, and it can be kept at 1100° F. for a long time without losing much of the hardness. This enables such a steel to be used for a cutting tool at so rapid a speed that its point becomes red with the heat of friction without losing its hardness for several hours. The carbon in these high-speed steels usually is only 0.60%, because the hardness then is sufficient and the toughness is greater than in a tool steel of carbon of 1% or over. Frequently, some chromium is used to intensify the hardness, and some vanadium to increase the strength. A great variety of analyses and heat treatments is employed, with a general average of 0.60% C, 16% to 20% W, 2% to 4% Cr, and 1% V. 18% W, 4% Cr, 1% V is a common composition in the United States. Before use, the steel is heated to near the melting point—treatment that would ruin ordinary steel—and then is cooled with moderate rapidity, as by holding it in an air-blast, or quenching it in oil. The heating and forging of the steel requires great care, and the proper directions for each brand should be obtained from the manufacturer.

**Molybdenum in High-speed Steel.**—Sometimes molybdenum is used in high-speed steel. It takes only one-half as much molybdenum to form $Mo_2C$ as tungsten required to form $W_2C$. Molybdenum steels are more difficult to make and handle. Molybdenum is also sometimes used to replace a part of the tungsten.

**Heat Treatment for High-speed Steel.**—High-speed steel is heated to about 2300° F. and cooled with moderate rapidity—as quenching in heavy oil, or subjecting to a blast of cold air. This treatment, which would be ruinous to ordinary steel, suffices to confer the high-speed qualities. It has been suggested that the reason for this is the behavior of carbide of tungsten as distinguished from that of carbide of iron. Tungsten has an atom of large size, which, therefore, diffuses very slowly in a solid solution. When steel is heated to about 2300° F. and cooled with moderate rapidity, the effect is to form and retain a double carbide of tungsten and iron, probably only partially separated from the solid solution and in extremely small size—perhaps colloidal. The result is similar to the extremely fine dispersion of $Fe_3C$ to which is ascribed by many metallurgists the hardness of quenched carbon steel. But when quenched carbon steel is heated to 400° to 600° F., the $Fe_3C$ particles begin to grow by diffusion and accretion. Even before reaching these temperatures, the hardness begins to decrease. Some claim that other crystals in the quenched steel also grow. In any event, the hardness is decreased as the extremely fine state of dispersion is decreased. In high-speed steels, the iron-tungsten carbide is so stable and diffuses so sluggishly that the particle size does not grow until the steel reaches a red heat. The persistent critical dispersion of the double carbide is said also to prevent the growth of other crystals in the steel. This explanation has been offered for the retention of hardness in high-speed steel up to red heat.

**Other Tungsten Steels.**—The Alloys of Iron Research Committee published a book on the Alloys of Iron and Tungsten in 1934, which contains very complete information on this subject. Tungsten and molybdenum both have more powerful effects than any other element in increasing the strength of steel at temperatures of 500° F. to the melting point. Five percent to 7% tungsten is used in permanent magnet steels together with 0.70% to 0.75% carbon. Before magnetizing, these steels should be hardened by quenching in water at a temperature between 1470° and 1600° F. The addition of 2% chromium to tungsten magnet steel improves its properties.

**SILICON STRUCTURAL STEEL.**—Silicon has the effect of moving to the left the point $S$ in the diagram in Fig. 6. Thus steel with 1% to 1.50% Si and about 0.35% C will be almost free from large Fe crystals. It, therefore, will be much stronger than the same carbon steel without silicon and will have almost equal ductility, because it will have considerable Fe in the form of small-sized crystals. Silicon structural steel has come into considerable use for bridges, as it has almost equal physical properties in strength and ductility to nickel steel and is much less expensive. From 0.90% to 1.50% Si usually is used in structural steels. In 1933 the Alloys of Iron Research Committee published a comprehensive book on the alloys of iron and silicon.

**SILICON TRANSFORMER IRONS.**—The purest possible form of iron will make a very superior transformer steel if silicon is added to increase its electrical resistance, thereby reducing eddy currents, and to precipitate carbon from solid solution, thereby increasing magnetic permeability. As much as 0.015% C, and sometimes more, may be retained in steel in solid solution at atmospheric temperature. In this form carbon has a more damaging effect on magnetic permeability than the same amount of carbon in the form of $Fe_3C$ or graphite. Silicon precipitates the carbon from the solid solution and itself enters the steel in the form of a solid solution, probably as a compound FeSi. This solid solution increases the electrical resistivity of the iron. The best amount of silicon is 4.75%, but this increases the expense, because the steel is difficult to shear without cracking on the edges. Consequently, silicon transformer irons of 1.75% and 3.75% Si, respectively, often are used. Modern methods of heating, usually kept secret, have the effect of decreasing the brittleness and tendency to crack when sheared.

**CORROSION-RESISTANT SILICON CAST IRONS.**—Cast irons containing from 13% to 17% Si have considerable resistance to rusting and to attack by sulphuric, nitric, organic, and (to some extent) hydrochloric acids. They are much used in chemical manufacturing plants. Their most important drawback is their brittleness. They must be protected from shock and cannot be machined or forged. They must be cast in the form of bowls, because plates and bars will crack in cooling. They go under the name duriron, tantiron, corrosiron, thermisilid, elianite, etc. See p. 3–24.

**MEDIUM MANGANESE STEELS.**—Steel containing about 1.75% Mn was used tentatively for bridge construction, and has been used for railroad rails because of improved resistance to the formation of transverse fissures. It is stronger than carbon steel, but the full benefit of the properties can be obtained only by heat treatment of moderately light sections. Therefore, it is not entirely successful for structural work. This type of manganese steel, when made in low carbon, is used for carburizing parts. With carbon averaging about 0.30% it is used for machine parts, and it then is normalized and preferably further heat treated by quenching and drawing. In the automobile field, steel with slightly higher carbon, when heat treated, is used for bolts, yokes, flanges; and with carbon up to 0.60% is used for oil-hardened gears, axles, grinding balls, etc.

**WEAR-RESISTING MANGANESE STEEL.**—Steel containing about 13% Mn is in a state of solid solution when rapidly cooled from white heat to atmospheric temperature. This is the oldest alloy steel used in large quantities, and is especially advantageous because of its resistance to wear. For teeth of digging machinery, railroad rails on curves, and other parts requiring resistance to abrasion, it is unequaled. It has very high ductility and a moderately high tensile strength, but the yield point is only about $^1/_4$ of the tensile strength. In order to be ductile, it must be heated to about 1850° F. and quenched in water; and in order to retain its wear resistance, the surface must be constantly subjected to pressure or impact, as by digging broken rock, or grinding against hard surfaces.

**VANADIUM STEEL.**—Vanadium is a powerful deoxidizer, but if more than about 0.20% V is left in the steel, it becomes brittle. Vanadium inhibits the grain growth of steel above 1300° F. It is used in castings because it improves the grain size and is used in heavy forgings, especially locomotive forgings, when the carbon is about 0.50% and sometimes for hardened steels approaching 1% C. The most common use of vanadium is in combination with chromium for very strong and tough parts after quenching and drawing. It is used for carburizing parts, oil-hardened axles, shafts, gears, especially in automobiles. Chrome-vanadium steels of about 1% Cr and 0.15% V commonly are used for automobile coil and flat springs. Vanadium is also used largely for increasing the hardness of high-speed steel, tools, armor piercing projectiles, permanent magnets, etc.

**MOLYBDENUM STEEL.**—The Alloys of Iron Research Committee has published a book, The Alloys of Iron and Molybdenum, containing all available data on the alloys of these metals. Molybdenum increases the tensile strength of carbon steel with only a slight decrease in ductility. Like tungsten, it has the effect of increasing the strength of steel at high temperatures. It increases machinability, the range of temperatures used in heat treating, and is more important as an addition to other alloying elements, such as chrome-molybdenum, nickel-molybdenum, nickel-chrome-molybdenum, etc. Chrome-molybdenum steel is much used for the structural parts of airplanes because of the ease with which it can be fabricated and welded, and its high strength when heat treated. Molybdenum greatly improves cast iron in amounts from 0.5% to 1.5% Mo. In high-strength cast iron, it has about the same effect as the combination of 1.5% Ni and 0.5% Cr.

**SILICO-MANGANESE STEELS.**—Steel containing 1.75% to 2.25% Si and 0.60% to 0.90% Mn, after quenching and drawing, has high resilience and high strength with good ductility. It is used largely in the automotive and railroad field for coil and leaf springs.

**AUSTENITIC STEELS.**—Steels which are in the state of solid solution at atmospheric temperature are known as austenitic steels. They are characterized by great ductility and wear resistance. If the solid solution contains 12% or more of chromium, they also resist corrosion, by all agencies which do not corrode chromium. If they contain carbon, it may be necessary to cool them rapidly from about 1500° F. in order to retain all the carbon in solid solution. Without this treatment they do not resist corrosion or possess high ductility. The common austenitic steels are the 18% Cr 8% Ni steels, the high manganese steels, and steel containing more than 20% Ni.

**STEEL FOR SPRINGS.**—The preceding paragraphs may be summarized by saying that the steels chiefly used for springs are the chrome-vanadium and silico-manganese steels. Straight carbon-chromium or carbon-molybdenum steels are used; also chrome-molybdenum, chrome-silicon-manganese and silicon-vanadium. The manufacture of steel for springs is of prime importance, because the service of the material is seriously affected by imperfections on or near the surface of the coil or leaf spring. Great honest difference of opinion exists as to the best alloy steel for springs. Chrome-vanadium steel seems to have the best combination of strength, resilience and durability, but many claim that silico-manganese steel is less subject to surface defects. See also p. 10–03.

**STEEL FOR MAGNETS.**—Carbon steel containing about 1% C, and quenched from above the line *PSK* in Fig. 6, makes a good permanent magnet. If the carbon is reduced slightly and some alloying elements are added, such as from 1% to 6% Cr or from 5% to 6% W or, better yet, 2% to 10% Cr, 1% to 10% W, and about 1% Mo, with up to 36% Co, very much improved magnetic properties are obtained.

**STEEL FOR HEAT RESISTANCE.**—Steels containing tungsten or molybdenum retain strength better at high temperatures. Steels containing 17% to 20% Cr with 8% to 10% Ni resist scaling at high temperatures.

**NITRIDING.**—Since about 1925 steel has been hardened on the surface by a process known as nitriding instead of the familiar carburizing process. The great advantage in the nitriding process is that it involves no quenching. Therefore, members of a complicated shape or uneven cross-section can be treated with safety. The steel also has a greater hardness, ranging from 900 to 1200 Brinell, as compared with 650 for carburized surfaces. The members are stronger and are said to have slightly greater corrosion resistance. The disadvantage of the nitriding process is the expense, the expert ability required to perform it, and usually the long wait required for obtaining the finished article.

In the nitriding process, the steel articles are heated in an atmosphere of ammonia gas. It is common to nitride for 12 hours at 875° to 1000° F. and then follow with 12 hours at nearly 1200° F. The steel to be nitrided usually contains about 1.25% Al, with 1% to 1.50% Cr and 0.15% to 1% Mo. Before nitriding, the steel is given a double heat treatment for strength. The purpose of the aluminum is to make a stable nitride. An innovation which has met with some success has been the use of nitriding for hardening the surfaces of cast iron objects.

## 9. STANDARD SPECIFICATIONS FOR STEEL PRODUCTS

The American Society for Testing Materials in the triennial issue of its Standard Specifications gives specifications for the composition, physical characteristics, heat treatment, etc., of many iron and steel products. The more important of these, from the 1936 issue, have been condensed in the following pages. Chemical and physical specifications are given for most of these products in Table 6 and the notes which accompany it.

Specifications for carbon and alloy steel forgings and for hot rolled bars and cold-finished bars and shafting are given in Tables 12 to 17. In all specifications, the following provision or its equivalent should be included:

The inspector representing the purchaser shall have free entry, at all times while work on the contract of the purchaser is being performed, to all parts of the manufacturer's works which concern the manufacture of the material.

Reference should be made to the latest issue of the Standard Specifications of the A.S.T.M. for complete specifications of any particular product.

Standard specifications for steels for use in the automotive industries are issued by the Society of Automotive Engineers. These are abstracted on pp. 2–37 to 2–48.

* B = Bessemer; H = open-hearth; E = electric furnace; C = crucible.

† These are tentative specifications and subject to yearly revision. The latest issue of the A.S.T.M. standards should be consulted.

[1] Acid steel

[2] Basic steel

[3] Cu, if specified, 0.20

[4] T.S. = tensile strength

[5] Bessemer steel

[6] Open-hearth steel

[7] Electric furnace steel

[8] Maximum

[9] Ladle analysis

[10] Check analysis

[11] For material over 3/4 in. thick, deduct 0.5% for each increase of 1/16 in. of specified thickness or diam. above 3/4 in. to a minimum of 24%

[12] Plates 3/4 in. thick or less

[13] Plates over 3/4 in. thick

[14] For material over 3/4 in. thick, deduct 0.25% for each increase of 1/32 in. over the specified thickness above 3/4 in. to a minimum of 20%

[15] Minimum

[16] Ni and Cr, 0.05 max., each. Preferably should be absent

[17] To be twisted with 1 twist in a length not more than 12 times thickness of bar

## Notes for Table 6

**Note 1.**—Test specimens shall be prepared for testing from material in the forged or rolled condition, except that specimens for annealed material, except eyebars, shall be from material as annealed for use, or from a short length of a full section from the same melt similarly treated. They shall be taken longitudinally and except as specified in notes 3, 4, and 5, shall be of full thickness of material as rolled.

**Note 2.**—Test specimens for plates, shapes and flats may be machined to form and dimensions of Fig. 2 (p. 7–54) or with both edges parallel.

**Note 3.**—Tension test specimens for material over 1 1/2 in. thickness or diameter, except pins and rollers, may be machined to a thickness or diameter of at least 3/4 in. for a length of at least 9 in., or may conform to dimensions of Fig. 2 (p. 7–54). For pins and rollers specimens shall conform to Fig. 2 (p. 7–54).

**Note 4.**—Bend test specimens: For material over 1 1/2 in. thickness (1 1/4 in. thick for A94–36) or diameter, except pins and rollers, may be machined to thickness or diameter of at least 3/4 in., or to a 1 × 1/2 in. section. For pins and rollers, specimens shall be

---

[18] Recorded only

[19] But not less than 14%

[20] Bars rolled from standard section tee rails

[21] 90-deg. bend

[22] For elliptical and helical springs

[23] For helical springs

[24] Cr = 0.90–1.10; V = 0.15 min.

[25] Elastic limit; determined by extensometer. See Note 43

[26] Through 120 deg.

[27] Through 150 deg.

[28] For material over 3/4 in. thickness or diameter, deduct 0.50% for each increase of 1/16 in. over the specified thickness or diameter

[29] In 18 ft.

[30] Bend test specimen for eyebar flats over 1 1/2 in. thick may be 1/2 in. sq. section. Corners may be rounded to a maximum radius of 1/16 in.

[31] If C exceeds 0.12%, Cr should be not less than 12.50%.

[32] For heat-resistant applications, C may be 0.40 max.

[33] For heat-resistant applications, C may be 0.35 max.

[34] For certain applications, Ni = 10.0–12.0% is desirable

[35] For particular and severe conditions, Mo = 2.00–4.00% sometimes is used as a constituent of this alloy. For free-machining or better non-seizing qualities, suitable combinations of Mo and S, or of Se and P, may be added as follows: Mo, 0.40–0.80; S, 0.20–0.40; Se, 0.20–0.35; P, max., 0.17.

[36] Cu = 0.90–1.20% required for heat-resistant castings.

[37] Also may be full annealed. See Note 48, p. 2–31.

1 × 1/2 in. section. Machined sides of rectangular specimens may have corners rounded to a radius of not over 1/16 in.

**Note 5.**—Test specimens for pins and rollers shall be so taken that axis is 1 in. from the surface of the material.

**Note 6.**—Number of tests: Two tension and two bend tests to be made from each melt; except that if material from one melt differs 3/8 in. or more in thickness, one tension and one bend test shall be made from both the thickest and the thinnest material rolled.

**Note 7.**—Variation of weight of plates: Cross-section or weight of each size structural shape, and each universal mill or sheared plate up to 36 in. wide and 2 in. thick, not to vary more than 2.5% from that specified. Sheared and universal mill plates may vary as follows, 1 cu. in. of rolled steel being assumed to weigh 0.2833 lb.: *a.* If ordered to weight per sq. ft., the weight of each lot in each shipment shall not vary from the weight ordered by more than the amount given in Table 7. *b.* If ordered to thickness, the thickness shall not vary more than 0.01 in. under that ordered. The overweight of each lot in each shipment shall not exceed the amount given in Table 8.

### Table 7.—Permissible Variations of Plates Ordered to Weight*

| Ordered Weight, lb. per sq. ft. | Permissible variations in average weights per sq. ft. of plates for widths given, expressed in percentages of ordered weights. | | | | | | | | | | | | | | | | | |

**Note 8.***—Elongation in 8 in., % min., = 1,500,000/tensile strength.

**Note 9.**—One tension and one bend test to be made from each melt; if two bars from one melt differ 3/8 in. or more in thickness or diameter, one tension and one bend test shall be made from both greatest and least diameters rolled. Test specimens to be full diameter of bars as rolled. Cold-drawn bars to be normalized before testing.

**Note 10.**—Permissible variations in diameter of rivet bars is as follows:

| Diameter...... | | Up to 1/2 in. incl. | Over 1/2 up to 1 in. incl. | Over 1 up to 2 in. incl. |
|---|---|---|---|---|
| Permissible... Variation.... | over | 0.007 in. | 0.010 in. | 1/32 in. |
| | under | 0.007 in. | 0.010 in. | 1/64 in. |

**Note 11.***—Elongation in 8 in., %, min., = 1,400,000/tensile strength.

**Note 12.**—Steel for plates or shapes over 7/16 in. thick which are to be punched, are to be made only by open-hearth or electric furnace processes.

**Note 13.**—Plates over 2 in. thick shall conform to permissible variations over ordered thickness as given in Table 10.

**Note 14.**—Permissible variation in weight, expressed as percentage of nominal weight, of bar size angles, tees, zees and channels not to exceed the following: Thickness over 3/16 in., any dimension over 1 1/2 in., variation, ± 4%; all dimensions 1 1/2 in. and less, variation, ± 5%. Thickness 3/16 in. and less, any dimension over 1 1/2 in., variation, ± 6%; all dimensions 1 1/2 in. and less, variation, ± 7%.

**Note 15.**—Permissible variation in cross-sectional dimensions of rounds, squares, and hexagons, not to exceed the following:

| Dimensions, in............ | up to 1/2 | 1/2–1 | 1–2 | 2–3 | 3–5 | 5–8 |
|---|---|---|---|---|---|---|
| Variation over, in.......... | 0.007 | 0.010 | 1/32 | 3/64 | 3/32 | 1/8 |
| Variation under, in......... | 0.007 | 0.010 | 1/64 | 1/32 | 1/32 | 1/16 |

Permissible variation in cross-sectional dimensions of flats not to exceed the following:

| Dimensions, in............... | Up to 1* | 1†–2* | 2†–4* | 4†–6* |
|---|---|---|---|---|
| Variation in width, in......... | + 1/32, − 1/64 | + 3/64, − 1/32 | + 1/16, − 3/64 | + 3/32, − 1/16 |
| Variation in thickness, in. | | | | |
| 3/16 in. thick and under..... | ±0.006 | ±0.008 | ±0.010 | ±0.010 |
| 3/16–1/2 in.*†.............. | ±0.008 | ±0.012 | ±0.015 | ±0.015 |
| 1/2–1 in.*†................ | ±0.010 | ±0.015 | ±0.020 | ±0.020 |
| 1–2 in.*.†................. | ....... | ± 1/32 | ± 1/32 | ± 1/32 |

**Note 16.**—Two tension tests and two cold bend tests shall be made from each melt of structural steel and steel for cold bending, except that one tension and one cold bend test is sufficient for melts of less than 25 tons. Two tension and two cold bend tests shall be made from each melt of rivet steel. If material from one melt varies 0.0150 in. or more in thickness, the thickest and thinnest material shall each be represented by one tension and one bend test, regardless of the weight of the melt.

**Note 17.**—Minimum elongation in 2 in. = 1,600,000/tensile strength, when specimen shown in Fig. 3, p. 7–54, is used.

**Note 18.**—Cross-section or weight of each piece of steel shall not vary more than 2.5% from that specified, except that sheared plates, ordered by weight per sq. ft., shall not vary more than the amount given by Table 7. When ordered to thickness, no plate shall vary more than 0.01 in. under thickness specified. Overweight in each shipment shall not exceed the values given in Table 8.

---

* For structural steel over 3/4 in. thick, 0.25% is to be deducted from the percentage specified by the formula, for each increase of 1/32 in. of the specified thickness above 3/4 in., to a minimum of 18%. For steel under 5/16 in. thick, 1.25% shall be deducted for each decrease of 1/32 in. of the specified thickness below 5/16 in.

† For plain and deformed bars over 3/4 in. diameter or thickness, a deduction from the percentage of elongation of 0.25% shall be made for each increase of 1/32 in. of specified thickness or diameter above 3/4 in. For bars under 7/16 in. diameter or thickness, a deduction of 0.5% shall be made for each 1/32 in. decrease of thickness or diameter below 3/16 in.

**Note 19.**—Permissible variation in thickness of plates ordered to weight is not more than 0.01 in. under thickness specified. Overweight in each shipment shall not exceed values given in Table 8.

**Note 20.***—Elongation in 8 in., %, min., = 1,400,000/tensile strength.

**Note 21.***—Elongation in 8 in., %, min., = 1,300,000/tensile strength, but not less than 16%.

**Note 22.***—Elongation in 8 in., %, min., = 1,200,000/tensile strength.

**Note 23.***—Elongation in 8 in., %, min., = 1,250,000/tensile strength.

**Note 24.***—Elongation in 8 in., %, min., = 1,125,000/tensile strength.

**Note 25.***—Elongation in 8 in., %, min., = 1,000,000/tensile strength.

**Note 26.**—Tension and bend test specimens from plain or deformed bars shall be of full section of bars rolled. For tension tests of deformed bars, sectional area used for unit stress determination to be calculated from weight of test piece.

**Note 27.**—Tension and bend test pieces for cold twisted bars to be taken from finished bar without further treatment.

**Note 28.**—Permissible variation in weight: Bars $^3/_8$ in. diameter or over, ± 3.5%; bars under $^3/_8$ in. diameter, ± 5%.

**Note 29.**—One tension and one bend test to be made from each lot of 10 tons or less of each size of bar rolled from rails varying not more than 10 lb. per yd. in nominal weight.

**Note 30.**—Permissible variation in diameter or thickness of rounds and squares is as follows: Up to $^1/_2$ in. incl., ± 0.007 in.; over $^1/_2$ to 1 in. incl., ± 0.010 in.; over 1 to 2 in. incl., ± 0.016 in. Permissible variation in dimension of flats: Variation in width, flats 1 to 2 in. incl., + 0.030 in., − 0.015 in.; flats over 2 to 4 in. incl., + 0.047 in., − 0.015 in.; flats over 4 to 6 in. incl., + 0.062 in., − 0.032 in. Variation in thickness, all widths, up to $^3/_8$ in. thick incl., + 0.015, − 0.005; over $^3/_8$ to $^5/_8$ in. thick, incl., + 0.015 in., − 0.010.

**Note 31.**—Class K for forgings for main- and side-rods, straps, piston rods and all other forgings which are to be machined with milling cutters or complicated forming tools.

**Note 32.**—Tension and bend test specimens to be taken from full size prolongation of any forging; may be taken from forging itself with a hollow drill, if approved by purchaser. Axis of specimen shall be located at any point midway between center and surface of solid forgings, midway between inner and outer surfaces of bored forgings, and parallel to axis of forging in direction in which metal is most drawn out. Tension test specimens to conform to dimensions of Fig. 2 (p. 7–54). Bend test specimens to be $^1/_2$ in. square section, with corners rounded to radius of not over $^1/_{16}$ in.; need not be over 6 in. long.

**Note 33.**—One tension test and one bend test (if specified) to be made from each tempering charge, or from each quenching charge if more than one is represented in a tempering charge. If more than one melt is represented, tests shall be made from each melt. If more than one class of forgings (by size) is represented, tests shall be made from each class.

**Note 34.**—Elongation in 2 in. = (2,100,000/tensile strength), but not under 20.5%.

**Note 35.**—Reduction of area = (4,100,000/tensile strength), but not under 39%.

**Note 36.**—Elongation in 2 in. = (2,000,000/tensile strength), but not under 20.5%.

**Note 37.**—Reduction of area = (3,800,000/tensile strength), but not under 39%.

**Note 38.**—Elongation in 2 in. = (1,900,000/tensile strength), but not under 19.5%.

**Note 39.**—Reduction of area = (3,600,000/tensile strength), but not over 37%.

**Note 40.**—Elongation in 2 in. = (1,800,000/tensile strength), but not under 19%.

**Note 41.**—Reduction of area = (3,400,000/tensile strength), but not under 36%.

**Note 42.**—Impact proof test required. Three methods of proof testing for quenched and tempered forgings are given in Table 11, which represent practices of four companies. Practice A requires axles, shafts and similar forgings to undergo an impact proof test on a A.R.A. drop test machine, with supports spaced 3 ft. center to center. Two blows are struck with a tup weighing 1640 or 2240 lb. The forging is to have one of the points of support as near as practicable to one end for the first blow and as near as practicable to the other end for the second blow, the forging being turned 90 deg. on its longitudinal axis between blows. Practices B and C require forgings to have an impact proof test of one blow at the center of the forging by a tup delivering the number of ft.-lb. of energy shown in Table 11. Practice B carries the forging on rigid supports placed 5 ft. center to center. Practice C carries the forging on rigid supports at the end of the forging.

---

* For plain and deformed bars over $^3/_4$ in. diameter or thickness, a deduction from the percentage of elongation of 0.25% shall be made for each increase of $^1/_{32}$ in. of specified thickness or diameter above $^3/_4$ in. For bars under $^7/_{16}$ in. diameter or thickness, a deduction of 0.5% shall be made for each $^1/_{32}$ in. decrease of thickness or diameter below $^3/_{16}$ in.

**Table 11.—Proof Tests for Quenched-and-tempered Forgings**

| Diameter, in. | Practice A | | | | Practice B<br>Practice C | Diameter, in. | Practice A | | | | Practice B<br>Practice C |

| 7 1/2 | 4 | 3 | 3 | 1 | 4,700 | 11 1/2 | 15 | 3 | 11 | 1 | 14,000 |
| 8 | 5 | 1 | 3 | 8 | 6,000 | 12 | 17 | 4 | 12 | 8 | 15,000 |

**Note 43.**—The elastic limit shall be determined by an extensometer, reading to 0.0002 in., attached to the specimen at the gage markings. The testing machine shall be operated to increase the load on the specimen at a uniform rate. The load at which the rate of elongation shows a sudden increase determines the elastic limit.

**Note 44.**—Each type of steel is subdivided, according to the carbon content into seven grades of carbon steel, and eight grades of each type of alloy steel. Carbon ranges are as follows:

Carbon Steel. Type A

| Grade........ | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
|---|---|---|---|---|---|---|---|---|
| Carbon, %.... | 0.05–.15 | .15–.25 | .20–.30 | .25–.40 | .30–.45 | .35–.50 | .40–.55 | .45–.60 |

Alloy Steels, Grades B–H

| Grade........ | 11 | 12 | 13 | 14 | 15 | 16 | 17 |
|---|---|---|---|---|---|---|---|
| Carbon, %.... | 0.10–.20 | .15–.25 | .20–.30 | .25–.38 | .30–.43 | .35–.50 | .45–.60 |

When steel is to be used for case hardening purposes, manganese should not exceed 0.50%; when minimum carbon specified is 0.35% or over, manganese range may be specified as 0.30–0.60%.

**Note 45.**—Steel Tires: Class A, for driving tires for passenger locomotives; Class B, for driving tires for freight locomotives; tires for locomotive-truck, tender-truck, trailer and car wheels; Class C, driving tires for switching locomotives.

**Note 46.**—Tension test specimens representing each melt to be taken from test ingot taken during pouring of melt; each specimen shall have received approximately the same amount of work as tire which it represents. Test specimens to be as in Fig. 3,* the ends to be of a form to fit the holders of the testing machine in such a way as to cause the load to be axial. Tires to be grouped as to outside diameters and shipped in sets.

**Note 47.**—Unless otherwise specified, the content of carbon, silicon and manganese and other alloying elements shall be selected by the manufacturer to meet specified physical properties. The prescription of definite composition types of steel to meet various physical requirements is not to be recommended except by mutual agreement between purchaser and manufacturer. There are at present (1936) approximately 70 available alloy cast steels, many of which can be made to conform to the tensile requirements of a grade in any class listed by proper heat treatment. See Automotive Steels, pp. 2–37 to 2–48.

**Note 48.**—Full annealing consists allowing the casting to cool after pouring, to a temperature below the critical range, reheating to the proper temperature and cooling thereafter slowly in the furnace. Castings shall not be removed from the furnace until the furnace charge has fallen uniformly to at least 500° F.

**Note 49.**—Normalizing consists of allowing the castings to cool after pouring, reheating to the proper temperature, above the critical range, holding at that temperature for the proper time,† and cooling in still air at room temperature. Normalizing may be followed by a tempering or drawing treatment at a temperature below the critical range, but not less than 400° F.

**Note 50.**—Class C castings shall be heat treated by full annealing, or by normalizing, or by heating above the critical temperature, followed by rapid cooling. These treatments may be followed by a supplementary heating and rapid cooling. Rapid cooling may be by quenching, by spraying with a liquid, or by subjecting castings to a mechanical air blast. These operations may be performed one or more times. After rapid cooling, castings shall be tempered or drawn at a temperature of 400° F. or more to relieve cooling stresses. Liquid-quenched castings, excepting simple light section designs, shall be removed from the quenching bath before they attain room temperature, and immediately placed in a tempering or drawing furnace.

---

* For shape of tension test specimens, see Fig. 3, p. 7–54, under Standard Test Pieces—Methods of Testing.

† A common rule is 1 hr. per 1 in. thickness.

**Note 51.**—Tension test specimens and bend test specimens shall be prepared from test bars attached to castings. If this is impracticable, test bars shall be cast attached to special blocks. Test bars shall remain attached to the castings or blocks until submitted for inspection and shall be heat treated with the castings. Tension test specimens shall conform to dimensions of Fig. 3, p. 7–54. The end shall be of a form to fit the holders of the testing machine in such a way that the load shall be axial.

**Note 52.**—One tension test, and when specified, one bend test shall be made from each melt in each heat treatment charge.

**Note 53.**—An analysis of each melt of steel shall be made from drillings taken at least $^1/_4$ in. below the surface of a test ingot obtained during the pouring of the melt.

Purchaser may make analyses on samples obtained from a casting (A128–33), which shall be taken not less than $^1/_4$ in. below the surface of rough castings, or at the surface of castings finished by grinding or machining, provided that at least $^1/_4$ in. of metal has been removed from the casting at the point selected for sampling. Manganese steel may be drilled best after it has been annealed for several hours at from 900 to 1100° F.

**Note 54.**—Bend tests shall be required only when specified. For castings weighing not over 50 lb., test to destruction by pressure or blows, may be made by agreement, as an alternative to bend tests. One casting from each lot shall be so tested and shall show the material to be tough and ductile, and suitable for the purpose intended. Bend test specimens shall be $^1/_2 \times {}^3/_4$ in. and 12 in. long, poured in separate molds, from the same heat or melt of steel, and heat treated with the castings they represent, without being machined or ground. Test bars should be protected from oxidation by enclosing them in pipes or containers containing a small amount of carbonaceous material and suitably sealed to prevent contact of furnace gases with the test bars. When bend tests are specified, one test shall be made from each melt or heat of steel in each heat treatment charge.

**Note 55.**—Elongation in 8 in. = 1,600,000/tensile strength.*

**Note 56.**—Bars to be annealed by heating to 1450° F., holding at that temperature for 30 min., and cooling slowly in the furnace, or in still air. Tension test specimens to be full diameter of bar as rolled, and to be annealed. Two tension tests to be made for each melt. If melt is less than 30 tons, but one tension and one upset test are required. If thickness of material from one melt varies $^1/_4$ in. or more, one tension test is required from the thinnest and thickest sections. One upset test is required for each size of bar rolled from each melt. Test consists in hammering cold in a longitudinal direction, a specimen of length = ($1\ ^1/_4 \times$ diam. of bar), until its length is ($^3/_4 \times$ diam. of bar), without developing in the specimen seams or other injurious defects. Permissible variation in diameter or out of round of bars is as follows:

| Diam. of Bar, in. | Up to $^5/_{16}$ | $^5/_{16}$–$^7/_{16}$ | $^7/_{16}$–$^5/_8$ | $^5/_8$–$^7/_8$ | $^7/_8$–1 | 1–1 $^1/_8$ | 1 $^1/_8$–1 $^1/_4$ | 1 $^1/_4$–1 $^3/_8$ | 1 $^3/_8$–1 $^1/_2$ | 1 $^1/_2$–2 |
|---|---|---|---|---|---|---|---|---|---|---|
| Variation in Diam., in., ± | 0.007 | .007 | .008 | .009 | .010 | 0.012 | .014 | .016 | .018 | .022 |
| Out of round, in. | 0.010 | .011 | .012 | .014 | .015 | 0.016 | .018 | .022 | .026 | .030 |

**Note 57.**—Minimum elongation in 2 in. = 1,700,000/tensile strength, when 2 in. test specimen is used. (See Fig. 3, p. 7–54.)

**Note 58.**—Grade A castings are very soft and machinable in the as-cast, normal or full-annealed condition, due to low carbon. They are adapted to fusion fabrication with wrought parts.

**Note 59.**—Grade B castings, normalized, are intended for miscellaneous industrial applications. Grade B-1, full-annealed and Grade B-2, full-annealed, are used for castings whose member thickness or intended use render a full anneal desirable to develop the required physical properties. All three grades are easily machined with ordinary machine tools.

**Note 60.**—Grade H normalized and Grade H-1, full-annealed, are used for purposes calling for higher strength and lower ductility than are typical of other grades. They can be machined without difficulty by ordinary machine tools.

---

* For structural nickel-steel plates, shapes, and bars, over $^3/_4$ in. thickness or diameter, 0.25% is to be deducted from the percentage specified by the formula for each increase of $^1/_{16}$ in. of thickness or diameter above $^3/_4$ in., to a minimum of 14%. For material under $^5/_{16}$ in. thickness or diameter, deduct 1.25% for each decrease in thickness or diameter of $^1/_{32}$ in. below $^5/_{16}$ in.

**Note 61.**—Tension and bend test specimens are taken from test bars attached to separately-cast blocks, and conform to the dimensions of a 2-in. test specimen. See Fig. 3, p. 7–54. Bend test specimens are to be machined to 1 × $^1/_2$ in. cross-section with the corners of the machined edges rounded to a radius of not over $^1/_{16}$ in.

**Note 62.**—Bend test required only when specified; it consists of bending specimen through 90 deg. around a 1-in. pin.

**Note 63.**—Bend test not required.

**Note 64.**—Bend test required only when specified; it consists of bending specimen through 120 deg. around a 1-in. pin.

**Note 65.**—Since corrosion resistance and heat resistance are of prime importance, tension tests and bend tests shall be made only when specified, in which case one tension test and one bend test shall be made from each melt. An average of three Brinell readings shall be taken as the Brinell hardness number.

**Note 66.**—Heat treatment consists of normalizing at not less than 1875° F., drawing at 1100–1350° F., and cooling in air.

**Note 67.**—Heat treatment consists in annealing at 1450–1550° F., cooling in furnace to 1100° F., and removing to cool in air. The steel should be cooled rapidly between 1050–900° F. to avoid inter-crystalline precipitations.

**Note 68.**—Heat treatment consists of annealing at 1450–1550° F., cooling in furnace to 1100° F., and cooling in air from 1100° F. Heavy castings may be cooled in water from 1100° F. to obtain maximum impact toughness. Castings of small dimensions may be quenched from 1650° F. to obtain best machinability.

**Note 69.**—Heat treatment consists in heating to a sufficient temperature for a long enough time to insure solution of carbides, and cooling at a rate to insure their retention in solution. If relief of quenching strains is desired, castings may be drawn at a temperature of 800° F., maximum, for not over 2 hours.

**Note 70.**—Heat treatment consists of heating to 1875° F., minimum, and quenching in air or water. Intricate castings may be drawn for strain relief at 800° F. maximum.

**Note 71.**—Heat treatment not required.

**Note 72.**—Heat treatment consists in heating to 1900° F. and quenching in water or in air. Oil may be used if water quenching is too drastic. Intricate castings may be drawn for strain relief at 800° F. maximum.

**Note 73.**—Values given for physical properties apply to heat-resistant alloy only when carbon does not exceed 0.30%. With higher carbon, ductility is lowered.

**Note 74.**—Tension test specimens shall conform to the dimensions of Fig. 3 (see p. 7–54.) Test coupons shall be cast attached near the end of each locomotive frame, to each locomotive cylinder, to each wheel center and to each other casting weighing over 100 lb., except as otherwise provided. Test castings shall remain attached to the castings throughout annealing and until the castings are presented for inspection. If the design is such that the test coupon cannot satisfactorily be attached to the casting, it shall be attached to a runner connected with the casting.

One tension test shall be made from a location near each end of every locomotive frame and one tension test may be made from each wheel center and each locomotive cylinder casting, and at least one tension test shall be made from one wheel center and one locomotive cylinder from each melt. One tension test shall be made for each melt represented by the castings covered by the specifications, except locomotive frames, wheel centers, and locomotive cylinders, as provided for above. For castings weighing not more than 150 lb. each, a test to destruction may be substituted for the tension test.

**Note 75.**—Castings shall not vary more than 5% above nor more than 3% below the weight agreed on as normal for the casting.

**CARBON STEEL AND ALLOY STEEL FORGINGS** (A.S.T.M. Designation A18–30).—Specifications cover the following classes of forgings: Class A which may be welded or case hardened. Class B, mild steel forgings for structural purposes, minor ship fittings, etc. Class C, mild steel forgings for structural purposes, ships, etc. Classes D, E, F, G, H, and I, various machinery forgings depending on design and stresses and services to be imposed. Classes K, L, and M, various machinery forgings, depending on design, stresses and services to be imposed, and on character of machining operations to be done. Steel shall be made either by the open-hearth or electric furnace, and shall conform to the chemical compositions of Table 12. The percentages of the elements specified in Table 12 shall be determined by an analysis of each melt, made from a test ingot taken during the pouring of the melt. Heat treatment, if required, shall consist of either annealing, or quenching and tempering, as specified. Annealing procedure consists in allowing the work, immediately after forging, to cool below the critical range under conditions that will prevent injuries by too rapid cooling, followed by uniform reheating to the proper temperature to refine the grain, after which the work is allowed to cool uniformly.

Quenching and tempering procedure consists in cooling and reheating the work as in annealing practice, and then quenching in some medium under substantially uniform conditions for each quenching charge. Finally, the work shall be uniformly reheated to the proper temperature for tempering or drawing back and allowed to cool uniformly.

Tensile properties for the various classes are given in Table 13. The classifications by size of the forging shall be determined by the specified diameter or thickness which

* Specification covers forgings of a maximum outside diameter or overall thickness of ⋜ 20 in.
† U = untreated; A = annealed; QT = quenched and tempered.
‡ Specification covers forgings having a maximum outside diameter or thickness of not over 10 in. when solid, or not over 20 in. when bored.

governs the size of the prolongation from which the test specimen is taken. Yield point shall be determined by drop of the beam or halt in the gage of the testing machine. The elastic limit shall be determined by an extensometer, reading to 0.0002 in., the load at which the rate of elongation shows a sudden increase being taken as the yield point.

Tests shall be made as follows: Untreated forgings, one tension test from each melt; annealed forgings, one tension test from each annealing charge, but if more than one melt is represented in each charge, one tension test shall be made from each melt; quenched and tempered forgings, one tension test from each tempering charge, but if more than one quenching charge is represented in a tempering charge, or more than one melt is represented in a quenching charge, one tension test shall be made from each quenching charge and melt, respectively; if more than one class of forgings by size is represented in any lot, one test from a forging of each class by size shall be made. Tests shall be made only after final treatment of the forgings.

Tension test specimens shall be taken from a full size prolongation of any forging. On forgings with large ends or collars, the prolongation may be of the same cross-section as that of the forging back of the end or collar. Specimens may be taken from the forging itself with a hollow drill, if approved by the purchaser. The axis of the specimen shall be located at any point midway between the center and surface of solid forgings, and at any point midway between the inner and outer surfaces of bored forgings, and shall be parallel to the axis of the forging in the direction in which the metal is most drawn out. Specimens shall conform to the dimensions of Fig. 3 (see p. 7–54). The ends shall be of a form to fit the holders of the testing machine in such a way that the load shall be axial.

**COMMERCIAL COLD-FINISHED BAR STEEL AND COLD-FINISHED SHAFTING** (A.S.T.M. Designation A108–36).—Specifications cover rounds, square and hexagons of all sizes, and flats up to 6 in. wide, and shafting rounds up to 8 in. inclusive. Steel shall be made by the open-hearth or acid Bessemer processes. Open-hearth steel is understood to mean steel made in the open-hearth or electric furnaces. Bar steel shall conform to the chemical compositions specified in Table 14. Check analyses may be made by the purchaser from finished bars representing each melt of open-hearth and each melt or lot of bars of Bessemer steel. Maximum permissible variation from the specified analyses, as shown by the check analysis, is given in Table 14. The permissible variation from specified diameters of cold finished round bars or shaftings and distances between parallel faces of hexagon squares or flats is given in Table 15.

**COMMERCIAL QUALITY HOT-ROLLED STEEL BARS** (A.S.T.M. Designation A107–36).—Specifications cover round, squares, and hexagons of all sizes, and flats up to 6 in. wide, of steel made by the open-hearth or acid Bessemer process. Open-hearth steel

the average of melts made during each 8-hr. turn. Open-hearth steel shall be analzyed for carbon, manganese, phosphorus and sulphur for each melt. Check analyses may be made by the purchaser from finished bars representing each melt of open-hearth steel and each melt or lot of bars of Bessemer steel. Maximum permissible variation from the specified analysis, as shown by this check analysis, is given in Table 16.

Variation from specified diameter or distance between parallel faces shall not exceed the limits given in Table 17.

**DROP TEST FOR CARBON STEEL RAILS** (A.S.T.M. designation A1–36).—Physical qualities to be determined by drop test, with a 2000-lb. tup, with a striking face of 5 in. radius, and 20,000-lb. anvil block supported on springs. Test pieces to be placed head up, on supports which are part of or firmly secured to anvil, and which have bearing surface of 5 in. radius. Supports to be spaced 3 ft. between centers for rails up to and including 106 lb. per yard, and 4 ft. between centers for rails over 106 lb. per yard. Height of free drop of tup to be as follows:

| | | | | | | |
|---|---|---|---|---|---|---|
| Weight of rail, lb. per yd..... | 50–60 | 61–80 | 81–90 | 91–100 | 101–120 | 121–140 |
| Height of drop, ft........... | 16 | 17 | 18 | 19 | 20 | 22 |

Three specimens from each melt must endure, without fracture, one blow each of the tup. One specimen shall be given a sufficient number of blows to determine the exhausted ductility, reported inch by inch, over the entire 6-in. gage length. Permanent set measured by middle ordinate in inches in length of 3 ft. shall be recorded after the first blow on all specimens. Brinell hardness shall be determined on one specimen, by means of a 19 mm. ball, with a pressure of 100,000 lb. Elongation, permanent set and hardness are determined for information only. The fracture of nicked and broken sections of No. 1 rails shall be free from seams, laminations, cavities, interposed foreign matter or a distinctly bright or fine-grained structure.

## Automotive Steels

The Society of Automotive Engineers has issued specifications (see S.A.E. Handbook) for steels that cover practically all requirements for ferrous metal parts in the construction of automotive equipment. These specifications have been widely adopted by industry in general, and it is common practice to specify steel by its S.A.E. number.

**S.A.E. Steel Numbering System** comprises, in general, a series of four-digit numbers, the first digit of which indicates the type of steel as follows:

| | |
|---|---|
| Carbon steels........................ | 1 |
| Nickel steels........................ | 2 |
| Nickel-chromium steels............. | 3 |
| Molybdenum steels.................. | 4 |
| Chromium steels.................... | 5 |
| Chromium-vanadium steels.......... | 6 |
| Tungsten steels..................... | 7 |
| Silico-manganese steels.............. | 9 |

For simple alloy steels, the second digit, generally, indicates the approximate percentage of the predominant alloying element. The last two digits, usually, indicate the average

(*Continued on p.* 2–41)

carbon content in points, *i.e.*, hundredths of 1%. Thus, 2340 indicates a nickel steel of approximately 3% Ni (3.25–3.75%) and 0.40% C (0.35–0.45%); 71360 indicates a tungsten steel containing about 13% W (12–15%) and 0.60% C (0.50–70%). The prefix X is used to designate variations in the range of manganese, sulphur and chromium. The prefix T is used to differentiate the 1300 series of manganese steels of different manganese range, identified by the same number without the prefix. Table 18 shows the uses of the various S.A.E. steels. Table 19 gives the chemical composition and identifying numbers of various S.A.E. standard steels. The various steels are specified by chemical composition only, since the physical properties can be varied by heat treatment. Table 20, compiled from curves in the S.A.E. Handbook, 1936 edition, gives the effect of heat treatment on various steels.

## Notes to Table 19

**CHARACTERISTICS AND USES OF THE VARIOUS S.A.E. STEELS.**—The following notes are abstracted from the S.A.E. Handbook, 1936 Edition.

**CARBON STEELS.—S.A.E. 1010 and S.A.E. 1015.**—Made by two methods of manufacture, known as rimmed and killed steel, respectively. Rimmed steel is used for sheet, strip, rod, and wire where high surface finish is desired. Suitable for deep drawing operations, and for cold heading wire. Killed steel is preferable to rimmed steel for carburized parts, especially where both core and rim of rimmed steel are involved in heat treatment.

These steels are of low tensile values and should not be used where much strength is desired. Heat treatment by direct quenching does not increase strength or hardness materially, or improve machinability, but cold drawing or cold rolling increases strength and hardness about 20% as compared with the hot-rolled condition, which improvement is lost if the steel is heated to 1000° F. or more.

**S.A.E. 1020.**—Standard carburizing grade of carbon steel. Used for wrist-pins, cam shafts, drag links, welded tubing, and forged and automatic parts where high strength is not necessary. May be brazed, butt-welded and drawn, but is not as desirable for deep drawing as S.A.E. 1010. Is not recommended for smooth threading, turning or broaching. Does not respond materially to heat treatment unless carburized or cyanided.

**S.A.E. X1020.**—A high-manganese variant of S.A.E. 1020, with better machining and carburizing properties.

**S.A.E. 1025.**—Has fair machining properties. Forgings usually machine better without annealing, or by simple normalizing. Is not considered a carburizing steel, but is suitable for case hardening where core hardness is desirable.

**S.A.E. X1025.**—A high-manganese variant of S.A.E. 1025, with better machining and physical properties; used for hub and rim bolts, studs, etc.

**S.A.E. 1030.**—Responds well to heat treatment, and is used for forged, machined or cold worked parts requiring higher physical properties than are obtainable with the lower carbon steels. Machines satisfactorily either without annealing or by a simple normalizing. Used for seamless tubing, key stock, levers, rail brackets, etc. Suitable for case hardening where core hardness is desired or for large sections.

**S.A.E. 1035.**—Fair machining properties, suitable for small and medium size forgings of moderate physical properties. Used for wire and rod for cold upsetting. Bolts and screws made from it, less than 3/8 in. should not be quenched in water, because of danger of quenching fractures.

**S.A.E. 1040.**—A medium carbon steel of fair machining properties and deep drawing characteristics. Suitable for small and medium size forgings. Used for tubing, crankshafts, connecting-rods, tubular and solid axles, spring clips, levers, bolts, studs, etc. Quenching of thin sections or small diameters in water should be done with caution.

* Maximum. † Desired content; minimum = 0.15.

‡ Silicon range of all S.A.E. basic open-hearth steels shall be 0.15–0.30. For electric and acid open-hearth alloy steels silicon content shall be 0.15 minimum.

**S.A.E. X1040.**—A low-manganese variant of S.A.E. 1040, used where deep hardening properties are not required. More suitable for water quenching than S.A.E. 1040.

**S.A.E. 1045.**—A medium carbon steel used for larger sizes of automotive forgings, as crank-shafts, starter ring gears, axles and spline shafts. Quenching of thin sections or small diameter parts in water should be done with caution.

**S.A.E. X1045.**—A low-manganese variant of S.A.E. 1045 where deep hardening properties are not required. See also S.A.E. X1335.

**S.A.E. 1050.**—A medium carbon steel for larger sections than S.A.E. 1045. See also S.A.E. X1335.

**S.A.E. X1050.**—A low-manganese variant of S.A.E. 1050 for heavier forgings and sections.

**S.A.E. 1055.**—Used for hard-drawn, oil-tempered or patented spring wire, and for general coil spring purposes.

**S.A.E. X1055.**—Used for snap rings, cushion springs, lock and thrust washers, hard-drawn spring wire, etc.

**S.A.E. 1060.**—Used for the same purposes as S.A.E. X1055.

**S.A.E. 1065.**—Used for smaller sections of valve springs, hard-drawn spring wire and general purpose coil springs.

**S.A.E. X1065.**—Used for larger sections of coil springs of hard-drawn or oil-tempered wire, and heat-treated springs.

**S.A.E. 1070.** Used in cold rolled or planished form for clutch discs; in agricultural industry for mower sections, plow beams, etc.

**S.A.E. 1075.**—Used in agricultural industry for cultivator discs, coulter blades and plows.

**S.A.E. 1080.**—Used in agricultural industry for plowshares, twine holders, knotter discs, springs, molds, shovels, harrow and plow discs.

**S.A.E. 1085.**—Used for bumper bars, lock pins, clutch discs, leaf springs, music wire; in agricultural industry for mower knives.

**S.A.E. 1090.**—Used for steel balls, pins, keys, bumper bars, leaf and coil springs; in agricultural industry, for harrow and seeder discs, seat springs, hay rake teeth and bundle carrier teeth for binders.

**S.A.E. 1095.**—For uses similar to those of S.A.E. 1090.

**S.A.E. 1112.**—A Bessemer steel, often called screw stock. Used for studs, screw and automatic machine products. Has good machining properties, but is cold short and should not be used for vital parts. May be carburized and cyanided, but open-hearth steels are recommended where heat treating is required.

**S.A.E. X1112.**—A variant of S.A.E. 1112, in which sulphur is added to improve finish and machinability. Should not be used in vital parts.

**S.A.E. 1115 and S.A.E. 1120.**—Known as open-hearth screw stock; inferior in machining properties to S.A.E. 1112 and S.A.E. X1112, but have a better combination of strength and toughness. Used for case-hardened parts and for bending, swaging, riveting and forming operations.

**S.A.E. X1314 and S.A.E. X1315.**—Used for case-hardened parts where good machining properties are desired. S.A.E. X1314 is preferable for drastic quenching of light sections where core toughness is essential.

**S.A.E. X1330.**—A free-cutting manganese steel that may be substituted for S.A.E. 1035 and S.A.E. 1040 where improved machining, deeper hardening and higher physical properties are required.

**S.A.E. X1335 and S.A.E. X1340.**—Free cutting manganese steels that may be substituted for S.A.E. 1045 and 1050 where improved machining, deeper hardening, and higher physical properties are desired. They are oil-hardening steels, and care should be used in water quenching.

**S.A.E. T1330.**—A manganese alloy steel that for certain applications can be used interchangeably with other medium alloy steels of similar carbon content.

**S.A.E. T1335 and S.A.E. T1340.**—Manganese oil quenching steels that for certain applications can be used interchangeably with other medium alloy steels of similar carbon content. Great care should be used in water quenching.

**S.A.E. T1345 and S.A.E. T1350.**—See note T1335.

**NICKEL STEELS.—S.A.E. 2015.**—A 0.5% nickel steel applicable as a substitute for carburizing grades of plain carbon steel. Will harden from an oil quench and may replace carbon steel for carburized parts if distortion is a factor, and water quenching undesirable.

**S.A.E. 2115.**—A carburizing grade of 1.5% nickel steel, used as an economical substitute for S.A.E. 2315. Quenches readily in oil, but does not have toughness or strength equal to 3 $^1/_2$% nickel steels.

**S.A.E. 2315.**—Primarily intended for carburizing. Should be given a single quench after carburizing when maximum hardness only is required, and a double quench when maximum core refinement and case hardness are necessary. Has low critical points and the case quenches to file hardness in oil. If used for gears of high accuracy and high strength, carburizing preferably should be preceded by normalizing at least 50 deg. F. above carburizing temperature.

**S.A.E. 2320.**—Similar to and sometimes used interchangeably with S.A.E. 2315. In the higher carbon range, it shows marked increase in core hardness and should not be used for thin sections. Machinability better than S.A.E. 2315. See S.A.E 2315 for note on use in gears.

**S.A.E. 2330 and 2335.**—For agricultural, automotive and aviation parts requiring considerable strength and toughness. Have good machining qualities, but are not carburizing. Used for keys, heat-treated butts, screws, studs, nuts, levers, etc.

**S.A.E. 2340 and S.A.E. 2345.**—Used for structural purposes where great strength and toughness are required. Are sensitive to heat treatment, and water quenching is not recommended. Typical uses are propeller shafts, spline shafts, axle shafts, etc., and (S.A.E. 2345) gears.

**S.A.E. 2350.**—Used for oil-hardened gears and heat-treated parts of large section.

**FIVE PERCENT NICKEL STEELS.—S.A.E. 2515 and S.A.E. 2512.**—Used for carburized parts requiring exceptionally tough core after heat treatment. Will not give the surface hardness of some of the other steels. For excellent core toughness, carbon content should be held to 0.17% max. The steel then is known as S.A.E. 2512.

**NICKEL-CHROMIUM STEELS.—S.A.E. 3115 and S.A.E. 3120.**—Intended primarily for carburized parts, but are more responsive to heat treatment than the carbon steels. May be heat treated for structural parts requiring a certain degree of strength. Carburizing should be preceded by normalizing at 50° F. above carburizing temperature. Applications are ring gears and pinions, spline shafts and countershafts, transmission gearing, piston pins, etc.

**S.A.E. 3125 and S.A.E. 3130.**—Used for water-quenched parts where greater strength and toughness are required than is possible with plain carbon steels. Used for cylinder studs, steering arm bolts, keys, nuts, connecting-rod bolts and structural parts requiring good physical qualities.

**S.A.E. 3135 and S.A.E. 3140.**—Used for heat-treated structural parts where good physical properties are required. Typical applications are crank-shafts, axle shafts, spline shafts, links for drive chains, studs, screws, etc.

**S.A.E. X3140.**—A higher-chromium variant of S.A.E. 3140, used where improved hardening characteristics are desired for parts of large section.

**S.A.E. 3145 and S.A.E. 3150.**—Used for oil-hardened gears and structural parts of heavy section.

**S.A.E. 3215 and S.A.E. 3220.**—Used for carburized parts requiring greater core strength than is possible with S.A.E. 3115 and S.A.E. 3120. S.A.E. 3220 should be used only for massive sections. These steels are not recommended for water quenching. Should be preceded by normalizing at 50° F. above carburizing temperature, followed by an anneal for machinability.

**S.A.E. 3230 and S.A.E. 3240.**—For parts requiring higher physical properties than are possible with steels of lower alloy content, and especially for sections over 1 1/2 in. diameter. Not recommended for water quenching.

**S.A.E. 3245 and S.A.E. 3250.**—For oil-hardened machined or forged parts that require high physical properties, as axle shafts, gears, and similar heavy duty parts.

**S.A.E. 3312.**—For carburized parts requiring a core of high strength and toughness.

**S.A.E. 3325.**—An oil-hardening steel, sometimes used interchangeably with S.A.E. 3230 for parts requiring high physical properties and capable of resisting severe dynamic stresses. Not recommended for water quenching.

**S.A.E. 3335 and S.A.E. 3340.**—Used for structural parts requiring high physical qualities and ability to resist severe dynamic stress.

**S.A.E. 3415.**—For carburized parts with a core of very high strength and toughness.

**S.A.E. 3435.**—For parts subject to severe service conditions.

**S.A.E. 3450.**—Used interchangeably with S.A.E. 3240 and S.A.E. 3340 for heat-treated machined or forged parts that require exceptionally high physical properties and ability to resist severe dynamic stress.

**MOLYBDENUM STEELS.—S.A.E. 4130.**—A chromium molybdenum steel used for axles, steering knuckles, steering knuckle arms, and sheet and strip for aircraft. Care should be used in water quenching.

**S.A.E. X4130.**—A higher-chromium and lower-manganese variant of, and used for the same purposes as, S.A.E. 4130.

**S.A.E. 4140.**—Used for rear axles, front axle tubing, propeller shafts, transmission shafts and forgings for aircraft.

**S.A.E. 4150.**—Used for parts of heavy section.

**S.A.E. 4340.**—Suitable for oil-hardening gears, axle shafts, Diesel engine crank-shafts, and heavy duty shafting over 2-in. diameter, where high strength and anti-fatigue properties are required.

**Table 20.—Physical Properties of Certain S.A.E. Steels with Various Heat Treatments**

| Draw Temp., deg. F. | Tensile Strength, 1000 lb. per sq.in. | Yield Point, 1000 lb. per sq.in. | Reduction of Area, percent | Elongation in 2 in., percent | Rockwell Hardness | Tensile Strength, 1000 lb. per sq.in. | Yield Point, 1000 lb. per sq.in. | Reduction of Area, percent | Elongation in 2 in., percent | Rockwell Hardness |

**S.A.E. 4345.**—Used for large gears and shafting, rear axle shafts and heavy sections and parts where high tensile and anti-fatigue properties are essential. Often specified for axle shafts over 2 in. diameter.

**S.A.E. 4615 and S.A.E. 4620.**—Used for carburized gears, shafts and parts where high fatigue resistance and high tensile properties are requisite.

**S.A.E. 4640.**—See S.A.E. 4615.

**S.A.E. 4815 and S.A.E. 4820.**—Used interchangeably with 5% nickel steel for gears and carburized parts. Also used for steering knuckle pins, roller bearings, chain pins, and high strength bolts and studs. Have excellent core and surface hardness and good wear resistance.

**CHROMIUM STEELS.—S.A.E. 5120.**—A plain chromium alloy steel of deep hardening type. Hardens satisfactorily in oil. Equal in physical properties to S.A.E. 2320 and S.A.E. 3120, except that it does not have the tough fibrous core of nickel-chromium-steels.

**S.A.E. 5140.**—May be used interchangeably with S.A.E. 2340 and 3140 for heat-treated forgings requiring greater strength and toughness than are obtainable in plain carbon steel. Used for gears and shafts hardened by direct cyaniding.

**S.A.E. 5150.**—An oil-hardening chromium steel used for gears, shafts, thrust washers and springs. Is a deep hardening type.

**S.A.E. 52100.**—Used for races and balls or rollers of anti-friction bearings.

**CHROMIUM VANADIUM STEELS.—S.A.E. 6115 and S.A.E. 6120.**—Normally are fine-grained steels used for carburized parts such as shafts, rear axle and transmission gearing. Are interchangeable with other alloy steels of similar carbon content.

**S.A.E. 6125 and S.A.E. 6130.**—Suitable for oil- or water-quenched parts. Steels of over 0.30 carbon should not be quenched in water.

**S.A.E. 6135 and S.A.E. 6140.**—Used for studs, screws, connecting rods, axle shafts, propeller shafts and similar applications. S.A.E. 6140 sometimes is used for gears hardened by direct cyaniding.

**S.A.E. 6145 and S.A.E. 6150.**—Used for heat-treated forgings and machined parts subjected to severe conditions, and requiring high strength and anti-fatigue properties. Also used for leaf and coil springs, gears, shafts and heavy forgings.

**S.A.E. 6195.**—Principally used for balls, rollers and races of anti-friction bearings.

**SILICON MANGANESE STEELS.—S.A.E. 9255 and S.A.E. 9260.**—Used principally for leaf springs. Mn on the high side of the range is specified for leaf spring sections 3/8 in. and over, and on the low side of the range for sections under 3/8 in.

**CORROSION AND HEAT-RESISTING STEELS.**—(See also p. 3-19). **S.A.E. 30905 and S.A.E. 30915.**—Standard so-called 18-8 Cr-Ni stainless steel, suitable for heat resistance up to 1500 ° F. May be forged, riveted, welded, cold-worked and deep drawn. Do not respond to hardening treatment. Somewhat difficult to machine.

**S.A.E. 51210.**—A stainless steel used for strip, rod and wire, shafting, forging, tubing, nuts, rivets, etc., where corrosion resistance is required. Can be hammered, forged, cold-worked, welded and machined at reduced speeds. Resists oxidation up to 1200° F.

**S.A.E. X51410.**—A free-machining, high-sulphur variant of S.A.E. 51210. Contains also Zr, Se, Mo and Cu. Applicable to the same uses as S.A.E. 51210 but machines easily at the speeds and feeds used for ordinary steel. May be readily polished.

**S.A.E. 51335.**—Standard cutlery grade of stainless steel. Used only in the hardened condition. Should be forged between 2000 and 1600° F. Has air hardening properties, and must be annealed after forging if it is to be machined. Used for shafts, bushings and bearings subject to corrosive conditions. Will resist tarnish from vegetable and mineral oil, moist air, water, steam and alkalis. Will not resist hydrochloric, sulphurous or hydrofluoric acid.

**S.A.E. 51510.**—Used for same purposes as S.A.E. 51210, but only in annealed condition. Is somewhat superior to S.A.E. 51210 in corrosion resistance. Can be forged, cold-worked and welded, but is not a good machining steel. Used for automobile trim and for bright surfaces maintained under exposure to oxidizing conditions.

**S.A.E. 51710.**—Used solely for ornamental purposes. Is more corrosion resistant than S.A.E. 51510. Not susceptible to heat treatment except annealing.

# WELDING OF IRON AND STEEL

**By J. C. Hodge and R. E. Hiller**

## 1. TYPES OF WELDS

**WELDING** has been defined as a localized consolidation of metals, accomplished by the application of either heat or pressure or a combination of the two. The temperature for accomplishing welding may vary; the source of the welding heat may differ; and pressure may be applied by various means or methods. The several welding processes involve different sources and degrees of welding heat, and also may involve different methods of applying pressure. These variations serve as a basis of classifying welding processes. See Fig. 1.

**WELDING PROCESSES** are divided into two general groups: 1. Methods in which the joint surfaces are heated to within the plastic temperature range and pressure applied. 2. Methods in which the joint surfaces are heated above the melting temperature of the parent metal and fusion obtained without pressure (fusion welding).

Soldering and brazing are joining processes allied to fusion welding, in which junction is accomplished by fusion of an intermediate metal of relatively low melting temperature between the parts to be joined without fusing their surfaces. These processes will not be further described.

The two main divisions of the welding processes are further classified according to the source of heat; for example, the plastic welding processes into forge welding, electric resistance welding, and Thermit pressure; the fluid or fusion welding processes into gas, electric arc, and Thermit welding.

**FORGE WELDING** is the oldest form of welding. The parts to be joined are heated locally in a furnace to the plastic temperature range and then subjected to pressure by hammering or rolling either by hand or by machine. This process is used for a wide variety of applications, from the miscellaneous work of the blacksmith to the joining of steel plates up to approximately 2 in. thick in the fabrication of boiler drums and other pressure vessels. Large tonnages of lap-welded and butt-welded tubes have been produced by passing heated formed skelp through pressure rolls. Forge welding has been largely superseded by other more recent welding processes.

**RESISTANCE WELDING.**—The various electric resistance welding processes are in principle similar to forge welding, in that the weld is made by application of pressure while the surfaces being joined are heated to plastic temperature. All resistance welding processes involve heating the edges of the parts to be joined by the passage of a heavy current across the joint. Heat is generated locally at the joint by reason of the greater electrical resistance of the circuit at the joint contact surfaces. Either direct or alternating current may be used, but generally it is most convenient to use alternating current, since the desired high amperage at low voltage is readily supplied through suitable transformers. Because of the high current required and the necessary "push-up" forces, the surfaces which may be joined by this method are limited. For a given cross-section to be welded, the power requirements vary widely with the time interval of current

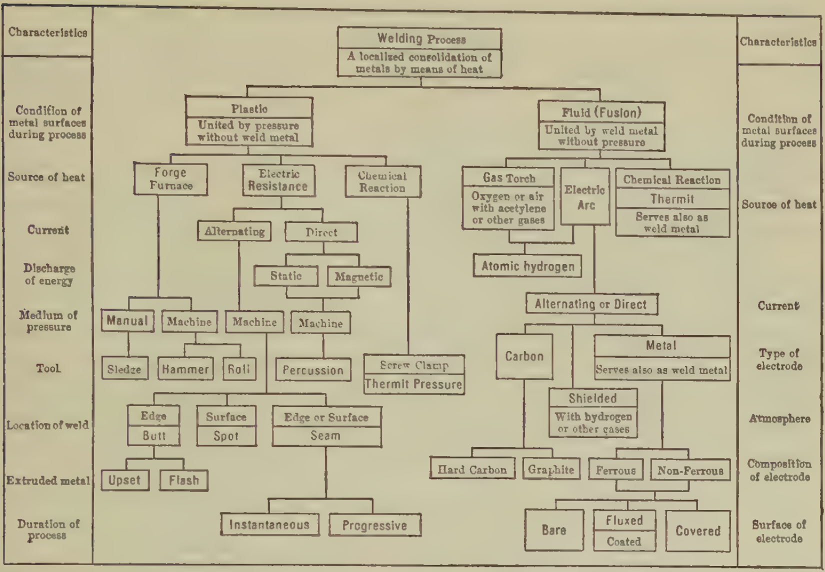

FIG. 1. Classification of the Principal Welding Processes

application to produce the weld. For the usual resistance weld, with low-carbon steel, requiring a heating period of several seconds, 30 kva. or more are required per square inch of weld surface. As the time interval is decreased the power requirement increases and, where welds are made in a fraction of a second, 1500 to 2000 kva. per sq. in. are not uncommon. The necessary pressure or push-up force applied after the joint surfaces have been heated to plastic temperature is approximately 5000 lb. per sq. in. of weld surface.

Resistance welding processes are particularly applicable to mass production, because special equipment is required for each type of welding job.

**Electrodes** for introducing the welding current into the work generally are faced with a hard copper alloy to avoid excessive replacement, which would be necessary if soft copper alone were used.

**Resistance Butt Welding.**—In resistance butt welding the parts to be joined are pressed into contact and electric current is passed through the grips (electrodes) and across the junction of the two parts. When the temperature of the contact surfaces has reached the plastic range, pressure is applied, and upsetting of the plastic metal to a greater or less degree accompanies the making of the weld.

**Electric Resistance Flash Welding** is a modification of resistance butt welding and is carried out in much the same manner. Contact edges are slightly separated, however, and arcing or flashing occurs from edge to edge of joint. This arcing may burn or flash off a considerable amount of metal at the joint before the ends become sufficiently hot to form the weld by pressure. During the flashing period this loss in metal is compensated by feeding the two edges together to provide a uniform distance between them. Pressure is applied after flashing has heated up the contact surfaces to welding temperature. Flash welding is applicable to the welding of larger joint areas than resistance butt welding. This method also requires less care in the preparation of joint surfaces and smaller current densities for satisfactory welding than does resistance butt welding. A hydrogen atmosphere often is maintained at the weld to prevent oxidation of the joint surfaces.

Both butt and flash resistance welding processes are widely used for joining ends of wires, bars and tubes. They have been more recently developed for producing tubing from flat strips by a continuous longitudinal butt weld as the formed strip passes through electrical contact rolls. In such tube welding processes very high currents are utilized, the weld being effected at point of contact in a fraction of a second.

After completion of the weld, it may be heat treated in the resistance welding machine, using the current to bring the portion between the grips or electrodes to the desired heat treating temperature.

**Resistance Spot Welding** is applied to the welding of overlapped metal sheets or other comparatively thin sections. The overlapped parts are held between electrodes, which apply pressure while electric current is maintained through them, and the current cut off before the pressure is released. The area welded is approximately the same size as the electrode tip, usually $^1/_8$ to $^1/_4$ in. diameter. Spot welding is particularly applicable to fabrication of metal sheets up to $^1/_4$ in. thick. Automatic equipment makes possible the production of many welds per minute.

**Shot Welding** is spot welding, in which an extremely high welding current is applied for a short period of time. This method is used, and is particularly valuable, for the welding of certain alloy steels, as nickel-chromium steels, where time at welding temperature is harmful to the metal. In spite of the large welding currents employed, the total heat required is relatively small because of the small time interval of current application.

**Resistance Seam Welding** may be considered as a series of overlapping spot welds, the electrodes generally being in the form of rolls which also transmit pressure as the overlapping sheets pass between them. Automatic equipment for this type of welding generally utilizes a current interrupter which so times the current impulses with relation to the speed of travel of the sheets that a series of overlapping spot welds actually results.

**Percussive Welding Processes** are a form of resistance welding in which electrical energy is discharged suddenly at the junction, accompanied by the application of pressure. Closing of the discharge circuit often accompanies the bringing of the two parts into contact with pressure. The energy discharge may be obtained from a condenser, or by the transformation, by the collapse of the field, of the energy stored in a magnetic field.

**THERMIT WELDING.**—In the Thermit welding process, superheated steel is obtained by the exothermic reaction which results when a mixture of iron oxide and aluminum is ignited. The iron oxide is reduced by the aluminum to iron. The resulting superheated steel is poured into a mold around the joint to be made, mold and joint having been preheated. The superheated steel resulting from the iron oxide-aluminum reaction has a temperature far in excess of the melting point of steel, and hence there is sufficient heat to produce fusion with the surfaces of the parts to be joined. The composition of the metal may be varied by the introduction of alloying elements. The process has been applied to all types of wrought or cast steel and iron. It is particularly applicable to repair of heavy sections and for making butt welds in pipe and rails.

**Thermit Pressure Welding.**—A modification of the Thermit process is the Thermit pressure method of butt welding. This is applicable to joining such parts as rails, tubes or bars which may be conveniently pressed together by end pressure. The surfaces to be joined are butted together and the Thermit slag and metal poured into the mold around the joint. The alumina slag produced in the Thermit reaction is poured into the mold first and covers the surfaces of the parts. The superheated metal does not come into direct contact with the parts, but heats them to the plastic temperature range. When the ends are heated, as judged by a suitable time interval, pressure is applied and produces what is essentially a forge weld.

**GAS WELDING.**—In this fusion welding process the welding heat is obtained from a gas flame, oxygen and acetylene being generally the gases used. Fuel gases other than acetylene may be used in combination with oxygen. With the oxygen-acetylene combination a flame temperature of 5,000 to 6,000° F. is obtained. By varying the proportions of oxygen and acetylene, a neutral, reducing, or oxidizing atmosphere may be obtained. For most purposes a neutral or slightly reducing atmosphere is used. The process is applied successfully to the welding of practically all metals. It is of particular advantage in making welds of any shape or position on comparatively thin sections, especially at sharp edges and corners. It is not, however, limited to thin sections, but may be satisfactorily used to produce welds in heavy metal parts. For joining thin parts, a filler metal may or may not be required, but for thicker sections a filler rod of suitable composition must be used. The reducing flame protects the molten metal from oxidation, but in the welding of some materials a flux is necessary to help remove oxides.

**ARC WELDING.**—In arc welding the welding heat is obtained from an electric arc formed between the base metal and an electrode, or between two electrodes. Welding current may be either alternating or direct. Depending on the character of the electrode, arc welding is designated as either *carbon arc welding* or *metal arc welding*. In both processes the heat is highly localized and the temperature of the molten metal is considerably higher than in gas welding. Arc voltages will vary from 15 to 45 volts and the arc current from 20 to 600 amperes, although some processes use current values as high as 2000 amperes. The magnitude of the current which can be successfully used depends on the size of the electrodes, thickness of parts being welded, and rate of weld travel.

In arc welding a molten pool forms on the work at the arc location. By manipulation of the electrode the molten pool is made to travel along the joint as desired. Additional metal is introduced by a filler rod with the carbon arc process. In the metal arc process, the molten metal is supplied by melting from the tip of the electrode. Metal arc welding is more readily adaptable to a wider variety of applications than carbon arc welding.

**The Carbon Arc Method** always is used with direct current, and for most purposes with the electrode negative in order to avoid excessive consumption of electrode and absorption of carbon in the weld metal. The procedure is essentially a puddling one, and is not adapted to welding in the vertical or overhead positions. Its best application is in automatic welding in the flat position, in which it is general practice to shield the arc and molten metal from the atmosphere by introducing a combustible material and fluxing agents into the arc. The method has had wide application for high-speed welding of thin sections in the fabrication of steel barrels, tanks and light tubular products. It also has been used for welding heavy sections in pipe and pressure vessels.

**The Metal Arc Method** carries metal across the arc from the electrode to the work in very small globules and deposits them in the molten pool on the work. The electrode is consumed and the metal deposited at a rate dependent on the current used. By proper choice of electrodes, either direct or alternating current may be used. The procedure is adaptable for welding of sections 1/16 in. thick or more, and may be carried out in flat, vertical, or overhead position. Best quality welding is obtained by protecting metal in the arc from oxygen and nitrogen of the atmosphere by covering the electrodes with suitable fluxing materials and combustible agents. These exclude oxygen and nitrogen from the arc and give a slag covering to the pool of molten metal. A wide variety of electrodes are available for particular applications. The method is the most versatile and most widely used of the various fusion processes.

**ARC WELDING EQUIPMENT.**—Either alternating or direct current may be used for arc welding, depending on the type of electrodes. Carbon electrodes, bare wire, and covered electrodes, with covering principally of combustible materials, generally require direct current. Covered electrodes, with covering principally of minerals are, in general, satisfactory for direct or alternating current. Alternating current has the advantage of eliminating arc disturbances created by magnetic fields, and is conveniently supplied from power lines through transformers.

**Motor-Generator Sets.**—The most satisfactory source of direct current is a motor-generator set. The most common type is a portable unit, supplying one arc. The generator is of the variable voltage type which adjusts its output voltage to the arc demands. A less common unit is a larger set, suitable for supplying several arcs. This type usually has a constant voltage type generator to supply 70 to 100 volts. The voltage for individual arcs is adjusted by resistances in each line.

Alternating current is supplied from single-phase transformers, either with variable voltage taps or with a variable inductance in each arc circuit to obtain desired current values. To obtain the necessary constant-current characteristics, inductance always is employed, although sometimes it is inherent in the transformer design. The magnitude of the constant current may be adjusted by varying the inductance.

**The Amount of Current Required** for each size of electrode will vary considerably with the type of coating and the mass of metal being welded. Approximate values are listed in Table 1. These values are for usual manual or automatic welding procedures. Some special methods use currents as high as 1500 to 2000 amperes with metal electrodes of 1/2 in. diameter or larger. One such method uses a bare electrode and keeps the arc completely buried in powdered flux.

**Electrodes.**—All important metal arc welds now are made with covered electrodes, because of the greater strength and ductility of the weld metal as compared to that obtained from bare wire. A large variety of materials is used for covering electrodes, but coverings may be grouped as those consisting principally of combustible material, those consisting principally of mineral substances, and those using a combination of

**Table 1.—Approximate Current for Various Electrodes for Welding Steel**

| Electrode Diameter, in. | Current Required, Amperes | | |
|---|---|---|---|
| | Carbon | Bare Wire | Heavy Coated Electrodes |
| 3/32 | ....... | 50– 80 | 60–100 |
| 1/8 | ....... | 75–125 | 80–150 |
| 5/32 | 40 | 100–175 | 125–200 |
| 3/16 | 75 | 150–225 | 150–250 |
| 1/4 | 100–200 | 200–300 | 225–400 |
| 5/16 | 200–400 | ....... | 275–500 |
| 3/8 | 300–500 | ....... | 350–700 |
| 1/2 | 400–700 | ....... | ....... |

combustible and mineral materials. The combustible type gives protection to the arc largely by producing a gaseous envelope about the arc which excludes oxygen and nitrogen. The mineral-coated types give protection by forming a sheath of molten slag about the arc and a heavy slag layer over the weld metal pool. The action of this slag may be considered similar to that of slag in steel-melting furnaces. The coverings of electrodes also aid in stabilizing the arc, and, to a very large degree, determine the welding characteristics of the electrode. Electrode coverings also may be used to some extent for introducing alloying elements into the weld metal.

**ATOMIC HYDROGEN WELDING** is actually a combination of both arc welding and gas welding. A stream of hydrogen is made to pass through an electric arc established between two tungsten electrodes. The heat of the arc causes disassociation of the molecular hydrogen to the atomic form. After passing through the arc the atomic hydrogen recombines into the molecular form, liberating the heat obtained originally from the arc. The atomic hydrogen flame is used in fundamentally the same manner as the oxy-acetylene flame. This process is of particular advantage for welding along edges and corners of thin sections. It is used for welding stainless steels. The hydrogen flame gives excellent protection to the readily oxidizable chromium in these steels. Filler metal of suitable composition may be melted in the atomic hydrogen flame as required.

## 2. PHYSICAL PROPERTIES OF FUSION WELDS IN STEEL

**CONDITIONS FOR SOUND WELDS.**—The physical properties of fusion welds depend, of course, on the relative freedom of the weld metal from defects such as porosity, entrapped slag, cracks, incomplete fusion, etc. Assuming that a sound weld has been obtained, physical properties will depend on the degree of protection which has been given to the molten metal from the gases of the atmosphere. Avoidance of contamination by nitrogen and oxygen is especially important in metal arc welding. Welds deposited with bare wire electrodes with no arc protection will contain approximately 0.10 to 0.15% N, and approximately 0.3% O. With a satisfactorily designed covered electrode, the deposited weld metal will contain less than 0.03% N, with oxygen correspondingly low. The effect of such contamination on weld metal physical properties may be best indicated by the following typical properties of metal arc welds in plain carbon steels using bare electrodes and covered electrodes:

| | Bare Electrodes | Covered Electrodes |
|---|---|---|
| Yield point, lb. per sq. in. | 35–40,000 | 45–55,000 |
| Ultimate tensile strength, lb. per sq. in. | 40–55,000 | 60–75,000 |
| Elongation in 2 in., percent | 0–10 | 20–38 |
| Endurance limit, lb. per sq. in. | 15–20,000 | 28–31,000 |
| Density | 7.50–7.70 | 7.80–7.85 |
| Charpy impact, ft-lb. | 3–8 | 20–45 |

The tensile strength of steel welds may be considerably increased over the above values by addition of suitable alloying elements, but in all cases, for a given composition, superior properties will be obtained in metal arc welding by using covered electrodes.

**SOUNDNESS OF FUSION WELDS.**—Producing welds by the gas or arc fusion processes introduces many variables of technique and operator skill which may cause mechanical defects in the weld. These may be gas pockets, entrapped slag from the electrode covering, zones of incomplete fusion between weld metal and base material, or cracks resulting from contraction stresses.

Several methods have been utilized for inspection of welds to detect such defects. The common medical stethoscope has been used to a limited extent, by detecting variation in sound issued at positions along the welds when struck by a hammer. This method is not very sensitive and is limited to welds up to about 1 in. thick. Magnetic methods have been used quite successfully in magnetic materials, to detect cracks at or near the surface of welds. They have not proved adaptable to detect defects far below the surface. The simplest of the magnetic methods consists of establishing a magnetic field approximately perpendicular to suspected defects and dusting a magnetic powder over the surface. The powder tends to concentrate at locations of fissures or cracks. The magnetic method may be used to advantage in some cases to supplement radiographic methods for the detection of small surface cracks which can not be disclosed readily by the x-ray method. The magnetic method also may be used to advantage for examining welds which can not for one reason or another be x-rayed.

The most thorough and reliable method of inspection is x-ray examination of the complete weld. The x-ray tube is placed on one side of the weld and photographic film on the opposite side. Excellent quality radiographs can be obtained which register the presence of all types of defects and give a clear picture of their size, location and distribu-

tion. This method may be used for examination of steel sections 4 1/2 to 5 in. thick, and will detect defective areas which are in thickness equal to 2% or more of the steel section. Gamma rays arising from radio-active materials may be used in the same manner as x-rays. They are particularly applicable to heavy sections and to use in locations where x-ray equipment can not be placed. Use of both x-rays and gamma rays require suitable precautions to avoid excessive exposure of personnel to the radiation. See X-ray Protection (U. S. Bureau of Standards Handbook HB20) for recommended practice.

**STRESSES IN WELDS.**—The thermal contraction of fusion welds, and the expansion and contraction of metal parts from the heat of welding, produces stresses of high magnitude in welded structures. The effects of these stresses are to distort the structure during welding and to create residual internal or *locked-up* stresses in the completed welds. By control of procedure, the degree of distortion, and the magnitude of the stresses may be considerably reduced. In thick sections and rigid structures, however, the completed welds invariably have residual stresses equal to the yield point of the material. It is not uncommon for these stresses to act in more than one axial direction, and to be of such magnitude as to cause fracture of the weld without any external loading. During welding, assembly of parts so as to allow for deformation due to contraction, and peening of the layers of weld metal will reduce the stresses. Their removal, however, is best accomplished by uniform heating, followed by slow cooling. For steel welds, heating the entire structure to 1100 to 1200° F. for one hour per inch of thickness is recommended. If it is possible to heat only part of the structure at a time, the temperature gradient between heated and unheated portions should not exceed 200° F. per foot. This stress relieving practice may be expected to reduce residual welding stresses to the approximate yield point value of the steel at the stress-relieving temperature, *i.e.*, 3000 to 8000 lb. per sq. in. for mild steels.

## 3. WELDING DESIGN

**ADVANTAGES OF WELDED CONSTRUCTION.**—The design and assembly of a structure with welded connections offer a number of advantages as compared to mechanical joints, such as riveting. The connections are simplified in that the joint generally is made direct, and no third member, as a butt-strap, is required. Welded joints permit placing the added metal exactly where needed, and produce an integral structure which, with mild steel, can develop 100% joint efficiency on any thickness of section. Elimination of extra material results in a weight saving of up to 25%. This saving in weight is an important consideration in transportation fields.

**FORMS OF WELDED JOINTS.**—Many forms of joints are used in fusion welding processes. Some of the more widely used are shown in Fig. 2. Drawings of welded construction should contain full information as to weld details, type of joint, dimensions of welds, etc. The American Welding Society has issued welding symbols which may be conveniently used on drawings specifying welding. See Figs. 5–8. In designing a welded structure, consideration also should be given to the following points:

**1.** The joint should be made as accessible as possible to the welding operator. This means that wherever possible welding should be done in the downhand position rather than taxing the skill of the operator by welding in the overhead position.

**2.** The dimensions of the joint should be such as to permit complete fusion through the thickness of the sections being welded. If incomplete fusion is obtained an undesirable stress concentration will be present. See Fig. 3.

**3.** Butt joints are preferable from the viewpoint of uniform stress distribution across the weld. In the case of fillet welds a 30 deg–60 deg. weld provides a more uniform transfer of stress through the weld than a 45 deg.–45 deg. weld. See Fig. 8.

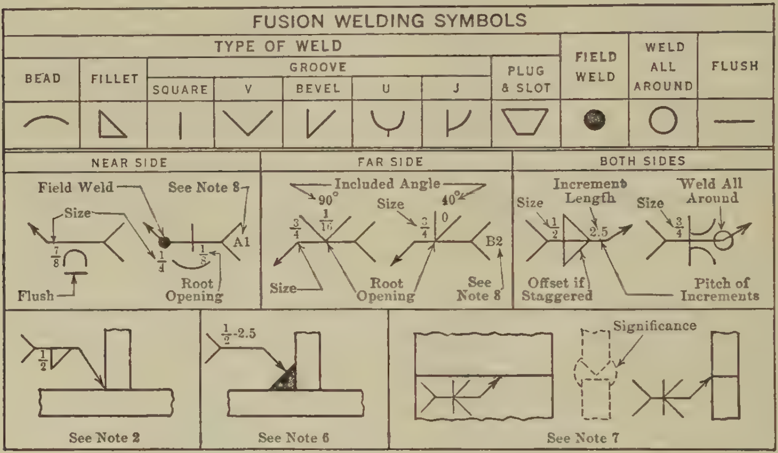

Fig. 5. Fusion Welding Symbols

1. In plan or elevation, near, far and both sides locations refer to nearest member parallel to plane of drawing and not to others farther behind.
2. In section or end views only, when weld is not drawn, the side to which arrow points is considered near side.
3. Weld symbols on both sides are of same size unless otherwise shown.
4. Symbols govern to break in continuity of structure or to extent of hatching or dimension lines.
5. All welds are continuous and of user's standard proportions, and all except V- and bevel-grooved welds are closed unless otherwise shown.
6. When welds are drawn in section or end views, obvious information is not given by symbols.
7. In joints in which one member only is to be grooved arrows point to that member.
8. Tail of arrow used for specification reference.

Note: All dimensions are in inches.

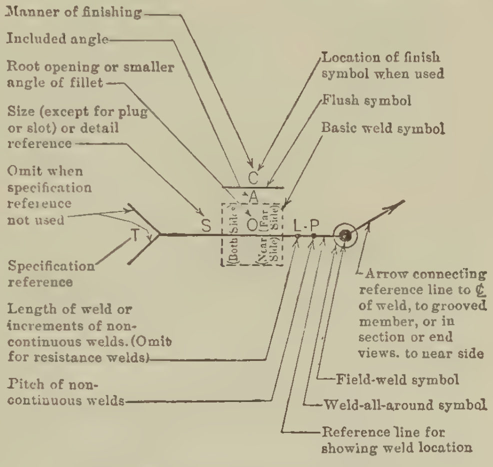
**4.** Where the structure previously has been a casting or built by riveting, and where the structure is being redesigned for welded construction, it should be appreciated that welding cannot be used interchangeably with the older riveted or casting design, and the designer should adapt his structure as far as possible to utilize the full advantages of welded construction.

**5.** Where distortion of the welded structure by reason of the contraction of the weld metal is liable to occur, and where the distortion is objectionable, the welds should, if possible, be so positioned that the contraction of the welds will tend to balance each other on each side of some central plane through the structure.

The design stresses will, of course, vary, depending on the quality of the welds and the conditions of service of the structure. For example, pressure vessels may be built on the basis of factors of safety of 4 or 5, corresponding to an allowable working stress of about 10,000 to 12,000 lb. per sq. in. (55,000 lb. per sq. in. tensile strength steel), while an open storage tank could reasonably employ much higher stresses. The allowable working stresses for welds of various types have been set by engineering codes governing different types of construction. A brief résumé of each code, including permissible working stresses for different types and classes of welded construction, is given below:



Manner of finishing
Included angle
Root opening or smaller angle of fillet
Size (except for plug or slot) or detail reference
Omit when specification reference not used
Specification reference
Length of weld or increments of non-continuous welds. (Omit for resistance welds)
Pitch of non-continuous welds

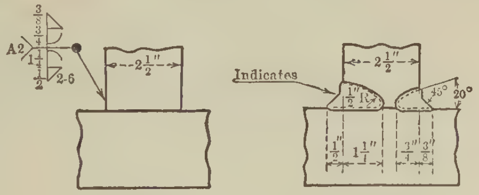
Fig. 7. Standard Location of Information on Welding Symbols

**A.S.M.E. Boiler Construction Code—Unfired Pressure Vessel Section.**—Rules for the fusion process of welding in this section are so drawn as to provide for three different classes of vessels as follows:



Sketch 1

Sketch 2

Fig. 8. Comparison between Symbolic and Verbal Methods of Welding Information

Interpretation of symbol: Double-fillet-welded, partially grooved, double-J, tee-joint with incomplete penetration. (Type of joint shown by drawing.) Grooves of standard proportions (which may be $1/2$ in. rad., 20° included angle, root edges in contact before welding) $3/4$ in. deep on far side and 1 $1/4$ in. deep on near side. $3/8$ in. continuous fillet weld on far side and $1/2$ in. intermittent fillet weld on near side with increments 2 in. long, spaced 6 in. center-to-center. All fillets standard 45° fillets. All welding done in field in accordance with welding specification number A2 (which may require, for example, that weld be made by manual D.C. shielded metal-arc process using high-grade, covered mild steel electrode; that root be unchipped and welds unpeened but that joint be preheated before welding).

I.—Paragraph U–68. Vessels may be used for any purpose when constructed in accordance with requirements, which are identical with those of the Power Boiler Section.

II.—Paragraph U–69. Vessels constructed in accordance with the rules of this paragraph may be used for any purpose except for containing lethal gases or liquids and/or liquids operating at a temperature in excess of 300° F., providing the plate thickness does not exceed 1 $1/2$ in., and the maximum pressure does not exceed 400 lb. per sq. in., nor at a temperature in excess of 700° F. This pressure limitation does not apply to vessels operated under hydraulic pressure at atmospheric temperature.

Requirements are as follows: 1. Main joints of double-welded butt type; 2. Vessels to be stress relieved when both the wall thickness is greater than 0.58 in. and the shell diameter less than 20 in., and for other wall thicknesses and shell diameters where the diameter is less than 120 $t - 50$, where $t$ = thickness, in.; 3. Qualification tests of welding operators at intervals of 6 or 12 months: *a*, tensile strength of weld not less than minimum of specified tensile range of plate for full section tension specimen, and not less than 95%

for reduced section tension specimen; *b*, bend test, ductility across weld, 20% minimum. 4. Factor of safety, 5; 5. Joint efficiency, 80%. 6. Allowable working stress as follows:

| | | |
|---|---|---|
| Minimum Tensile Strength of Plate | 55,000 lb. per sq. in. | 70,000 lb. per sq. in. |
| Allowable working stress, lb. per sq. in. | 8,800 | 11,200 |

III.—Paragraph U–70. Vessels constructed in accordance with the rules of this paragraph may be used for the storage of gases or liquids, except lethal gases or liquids, at temperatures not materially exceeding their boiling temperature at atmospheric pressure, and at pressures not to exceed 200 lb. per sq. in. and/or not to exceed 250° F.

Requirements are as follows: 1. Plate thickness not over $^5/_8$ in.; 2. Qualification tests of welding operators at intervals of 6 to 12 months; *a*, tensile strength of weld not less than 90% of minimum of specified tensile range of plate used for full section tension specimen and not less than 85% for reduced section tension specimen; *b*, bend test ductility across weld, 10% minimum.

Allowable working stresses are as follows:

| | | |
|---|---|---|
| Double-welded butt joints for all joints | 8,000 | lb. per sq. in. |
| Single-welded butt joints for girth or head joints | 6,500 | " |
| Double full-fillet lap joints for girth joints only | 7,000 | " |
| Plug or intermittent welds for girth or head joints | 5,600 | " |
| Single-welded butt joints and double full-fillet welds for longitudinal joints: | | |
| *a*, For thickness of less than $^1/_4$ in | 5,600 | " |
| *b*, " " " $^1/_4$ to $^3/_8$ in | 7,000 | " |

**A.P.I.–A.S.M.E. Unfired Pressure Vessel Code.**—This code covers the construction of vessels for use with petroleum liquids and gases. Stress relieving is required for plate thicknesses above 1 $^1/_4$ in., or when radiographing is not mandatory. Factors permitting various joint efficiencies are employed, these factors varying with type of steel plate, type of joints, and whether or not radiographing of the welded joints and stress relieving of the vessel has been employed, as follows:

| Steel: | Specification | Factor |
|---|---|---|
| Group A | A.S.T.M. A70, firebox grade only | 1.00 |
| | " A30, " " " | 1.00 |
| | " A149, " " " | 1.00 |
| | " A150, " " " | 1.00 |
| Group B | " A70, flange " " | 0.97 |
| | " A30, " " " | 0.97 |
| | " A149, " " " | 0.97 |
| Group C | " A7<br>" A10<br>" A113<br>Not to be used for plates thicker than $^5/_8$ in. or for metal temperatures above 450° F | 0.92 |
| Radiographing: | | |
| | Radiographed | 1.12 |
| | Not radiographed | 1.00 |
| Stress Relieving: | | |
| | Stress relieved | 1.06 |
| | Not stress relieved | 1.00 |
| Weld Joints: | | |
| | Double-welded butt joint and single welded butt joint with backing-up strip | 0.80 |
| | Single-welded butt joint without backing-up strip | .70 |
| | Double-full-fillet lap joint and single-full-fillet lap joint with plug welds | .65 |
| | Single-full-fillet lap joint | .55 |

For service temperatures below 650° F. the allowable working stress in tension and shear for carbon steel in this code is 25% of the ultimate strength in tension at atmospheric temperature. The allowable working stress of a welded joint, therefore, is

$$^1/_4\, S \times f_q \times f_r \times f_s \times f_w$$

where $S$ = ultimate tensile strength of steel, and $f_q$, $f_r$, $f_s$ and $f_w$ = respectively, the factors for plate quality, radiographing, stress relieving and weld joint. Thus welded joints on plate of 55,000 lb. per sq. in. minimum tensile strength of Group A, of the double-welded butt type, radiographed and stress relieved, would have an allowable working stress of

$$^1/_4\,(55{,}000) \times 1.00 \times 1.12 \times 1.06 \times 0.80 = 13{,}060 \text{ lb. per sq. in.}$$

Table 2 gives the probable combinations of construction factors and joint efficiency.

**Table 2.—Joint Efficiency of Various Types of Construction**

| Type of Joint | Joint Efficiency, percent | Radiograph Factor (1.12) | Stress Relief Factor (1.06) | Final Joint Efficiency for Groups of Steel, percent | | |
|---|---|---|---|---|---|---|
| | | | | A, Factor = 1.00 | B, Factor = 0.97 | C, Factor = 0.92 |
| Double-welded butt joint and single-welded butt joint with backing-up strip. | 80 | .......... | .......... | 80 | 78 | 74 |
| | | .......... | * | 85 | 82 | 78 |
| | | * | .......... | 90 | 87 | .......... |
| | | * | * | 95 | 92 | .......... |
| Single-welded butt joint without backing-up strip. | 70 | .......... | .......... | 70 | 68 | 64 |
| | | .......... | * | 74 | 72 | 68 |
| | | * | .......... | 78 | 76 | .......... |
| | | * | * | 83 | 81 | .......... |
| Double-full-fillet lap joint and single-full-fillet lap joint with plug welds. | 65 | .......... | .......... | 65 | 63 | 60 |
| | | .......... | * | 69 | 67 | 63 |
| Single-full-fillet lap joint. | 55 | .......... | .......... | 55 | 53 | 51 |
| | | .......... | * | 58 | 57 | 54 |

Note.—The asterisks in the columns Radiograph Factor and Stress Relief Factor indicate that these operations have been performed. For example, in Line 4, the factor under Column A = 80 × 1.12 × 1.06 = 95, and under Column B = 95 × 0.97 = 92.

**A.S.M.E. Boiler Construction Code—Power Boiler Section.**—The use of forge welding, electric resistance butt welding, or pressure Thermit welding, has been sanctioned for many years. The ultimate strength of the joint is considered as 35,000 lb. per sq. in. Allowable working stress on factor of safety of 5 is 7000 lb. per sq. in.

The rules for the fusion process of welding, adopted in 1931, apply only to drums and shells. The chief requirements are as follows: 1. Main joints are of double-welded butt type. 2. Main joints are radiographed. 3. Completed welded drum is stress relieved. 4. Test plate welded with drum: *a*, tensile strength of transverse specimen and all-weld-metal specimen to be at least that of minimum of the range of the plate; *b*, elongation of all-weld-metal tension specimen, 20% in 2 in. minimum; *c*, elongation of outer fibers of transverse bend test, 30% minimum across weld; 5. Carbon content of plate material, 0.35% maximum. 6. Factor of safety, 5. 7. Joint efficiency, 90%. 8. Allowable working stress of plate as follows:

| | | |
|---|---|---|
| Minimum Tensile Strength of Plate....... | 55,000 lb. per sq. in.* | 70,000 lb. per sq. in.* |
| Allowable working stress, lb. per sq. in., at temperatures up to 700° F.......... | 9,900 | 12,600 |

**Bureau of Marine Inspection and Navigation, U. S. Dept. of Commerce.**—The welding rules of this code, covering the construction of marine boiler drums and unfired pressure vessels, are similar to the requirements of the A.S.M.E. Boiler Construction Code.

**Bureau of Engineering, U. S. Navy Dept.**—These welding specifications establish for purposes of requirements as to design and tests of welded assemblies a classification of welded structures as follows:

- Class A—Pressure vessel welds.
  - Class A1—Fired pressure vessels such as boiler drums.
  - Class A2—Unfired pressure vessels.
  - Class A3— " " "
  - Class A4— " " "
- Class B—Structural welds.
  - Class B1—Moving machinery parts.
  - Class B2—Stationary machinery parts.
  - Class B3—Non-pressure vessels.
  - Class B4—Tack welding.

A joint efficiency of 90% is permitted on welds which have been radiographed. Otherwise the joint efficiency is taken as 80%.

**A.S.A. Code for Pressure Piping.**—This code covers construction requirements for various kinds of piping including piping for steam, gas, air and oil. Welding requirements involve qualification of welding operators. Stress relieving of pipe joints is mandatory when the pipe wall thickness is greater than 3/4 in., and the service temperature is in excess of 250° F. See Kent's Mechanical Engineers' Handbook—Power, p. 5–23, forming Vol. 2, of this series.

---

* Intermediate tensile strengths in proportion.

**National Board, Rules for Repair of Boilers by Fusion Welding.**—Rules for the repair of boilers by fusion welding have been issued by the National Bureau of Casualty and Surety Underwriters in co-operation with the National Board of Boiler and Pressure Vessel Inspectors. Copies of these rules may be obtained upon application to the National Bureau of Casualty and Surety Underwriters, 1 Park Avenue, New York City.

A number of other codes exist covering various types of welded construction. In general, all codes require qualification of welding operators, and most of them embody filler metal specifications in accordance with the requirements of the American Welding Society specification, issued August, 1933.

Some of the constructional codes issued by the American Welding Society are as follows: Code for Fusion Welding and Gas Cutting in Building Construction (*Jour.*, Am. Welding Soc., March, 1935). Specification for the Design, Construction, Alteration and Repair of Railway and Highway Bridges. Tentative Code for Fusion Welding and Flame Cutting in Machinery Construction. Marine Code for Welding and Gas Cutting, Part D, Rules for the Fusion Welding of Hulls and Hull Parts (*Jour.*, Am. Welding Soc., Feb., 1935).

## 4. WELDING OF VARIOUS MATERIALS

**STEELS.—General.**—The difficulty which may be encountered in the welding of various steels is, in general, in proportion to the hardening developed in the heat-affected zone along the weld. With high hardness, fine cracks or even complete fracture may result from welding stresses. As the carbon content of steel increases, the potential hardness increases, and the addition of alloying elements in general emphasizes the hardening effect.

Excessive hardening can be somewhat controlled by regulating the cooling rate from the welding temperature. With Thermit welding and Thermit pressure welding, a slow cooling rate can be obtained by the insulating effect of the mold surrounding the entire weld. With gas welding, particularly on thin sections, the torch can be used to heat the base materials and keep the zone adjacent to the weld sufficiently hot to retard cooling. With arc welding, the area of high temperature is very localized, and preheating of the parts sometimes necessary to obtain slow cooling and to reduce welding stresses. With a composition giving high hardness, more difficulty is likely to occur with heavy sections, and whatever welding method is used preheating will be necessary. Heating to 400 to 500° F. is effective and, depending on the steel and the particular structure, this temperature may need to be maintained until the weld has been stress relieved.

Variation in the quality of steel may result in welding difficulties even for grades normally considered weldable, such as plain carbon steels below 0.30% C. Fortunately, such difficulties are exceptional. No definite information is available as to the reasons for such difficulties, although it is generally conceded that trouble may occur because of excessive segregation in the steel, or because of the presence of abnormally large amounts of residual elements such as arsenic, copper, etc. Laminations in rolled steel products will, of course, produce welding difficulties, especially if the lamination extends along the joint edge.

**CASTINGS.**—Castings may be satisfactorily welded, provided rolled or forged steel parts of the same composition can be satisfactorily welded. This assumes that the casting adjacent to the weld region is sound and free from shrinkage cracks which otherwise would open under the contraction stresses during cooling from welding.

**IRON AND CARBON STEELS UP TO 0.35 PERCENT CARBON.**—Iron and plain carbon steels up to 0.35% C. are readily welded by all processes, and completed welds can be obtained with strength equivalent to the base materials. Preheating is not necessary except for extremely rigid joints where welding stresses become exceptionally high. In fusion welding, with gas or electric arc, filler metal of approximately 0.15% C. is recommended. With shielded arc methods (carbon or metal arc), ductile welds with strength of 60,000 to 70,000 lb. per sq. in. will be obtained. This strength can be increased to 70,000 to 80,000 lb. per sq. in., without loss of ductility, by small additions of alloying elements. Molybdenum in amounts of 0.2 to 0.4% is very effective.

Where stress relieving is required, heating at 1100 to 1200° F. for a period of one hour per inch of thickness is recommended.

**MEDIUM CARBON STEELS OF 0.35 TO 0.60 PERCENT CARBON.**—As the carbon content of steel increases above 0.35%, difficulty in welding is likely to develop. With thin sections and a flexible design, gas or arc welding may be used without preheating, but in joints over $^3/_8$ to $^1/_2$ in. thick, preheating is necessary. In oxygen-acetylene gas welding, better welds are obtained with a flame having excess acetylene. To develop equivalent strength in the weld, a low-alloy filler metal should be used for both gas and arc welding methods. A rod containing chromium and molybdenum is recommended. These steels are readily welded by the Thermit process.

Welds should be stress relieved at 1100 to 1200° F. and, where preheating has been necessary or with the higher carbon ranges, this stress relieving should be carried out before permitting the weld to cool below 300° F.

**HIGH CARBON STEELS OF 0.60 TO 1.50 PERCENT CARBON.**—Steels above 0.60 percent carbon may be welded quite satisfactorily by the Thermit process, and this method has been used considerably for butt welds in rails. Gas and arc welding can be done only with considerable difficulty, and the resulting welds are only fairly satisfactory. Gas welding is more easily performed. A joint can be made by arc welding by depositing low-carbon metal over the surface of each part and then making the arc weld between these low carbon surfaces. The resulting weld will, of course, have the properties of a low carbon weld.

**LOW-ALLOY HIGH-YIELD-STRENGTH STRUCTURAL STEELS.**—There are a considerable number of low-alloy steels especially designed to produce yield point values of 50,000 to 70,000 lb. per sq. in. and with ultimate strengths of 70,000 to 100,000 lb. per sq. in. Most of these steels have been produced with a low carbon content and no particular difficulty is encountered in welding them. In general, where carbon contents are 0.20% or less, gas or arc welding can be performed without preheating. With higher carbon contents, preheating will often be necessary. To develop weld strengths equivalent to the base material, it is necessary to use filler metal with some alloy content. Low carbon filler metal with alloy composition similar to the base materials usually can be used. Stress relieving should be carried out at 1100 to 1200° F.

**S.A.E. ALLOY STEELS.**—For welding of the S.A.E. alloy steels, the same general procedure may be used as for the alloy structural steels. The ease of welding will depend on the hardness developed in the heated zone. Where high hardness occurs, preheating to 300 to 500° F. will be necessary. Filler metal of similar alloy composition to the base material usually can be used.

**CHROMIUM STEELS OF 4 TO 6 PERCENT CHROMIUM** are definitely air hardening, even with low carbon content, and preheating at 300 to 500° F. is essential. Welds generally must be kept above 300° F. until annealed or stress relieved. Heat treatment after welding should be a full anneal or long time stress relieving at 1300 to 1350° F. The same procedure should be used with steels of 2 1/2% Cr. With such procedure, welds in these steels with carbon less than 0.20% are very ductile and equal to the base metal in every respect.

**CORROSION- AND HEAT-RESISTING STEELS** have high percentages of chromium or chromium and nickel, with low carbon content. Welding steels with 12 to 30% Cr requires preheating to above 200° F., and an annealing treatment after welding in order to obtain ductility. The lower chromium ranges, 12 to 16% Cr, may be welded without great difficulty if preheating precautions are taken. As the chromium content is increased, the welds are much less ductile, and the very high chromium range becomes very difficult to weld. Heat treatment should consist of annealing at 1450 to 1550° F. To maintain equivalent chromium content in the welds, filler metal should have a slightly higher chromium content than the base metal. Due to rapid carbon absorption in high-chromium steels, the carbon arc method is not suitable.

The stainless steels containing high percentages of both chromium and nickel are not subject to hardening from heat treatment and may be welded without difficulty. Typical steels of this group are: 18% Cr–8% Ni, 25% Cr–12% Ni, 25% Cr–20% Ni; there are many other variations of analysis. Welds in all of these materials are soft and ductile, and no heat treatment after welding is required, except as may be needed to improve corrosion resistance. In this respect the 18% Cr–8% Ni type is subject to serious loss of corrosion resistance, due to precipitation of carbides in the temperature range of 900 to 1500° F. For this reason, very low carbon contents (less than 0.07%) are desirable for these steels if they are to be welded. The carbides may be stabilized by addition of titanium or columbium, and steels so stabilized are recommended for welding. Filler metal also should be of the stabilized analysis. Titanium should be used in amounts of at least 6 times the carbon content, and columbium in amounts of at least 10 times the carbon content. If the 18% Cr–8% Ni steels are not of the stabilized type, heat treatment after welding should consist of heating to 1900 to 2100° F. followed by rapid cooling. In the higher alloy steels, carbide precipitation is not serious.

Because of higher electrical resistance and lower heat conductivity, electric welding of these steels requires about 10% lower current than carbon steels. Also, the high coefficient of expansion requires additional care to prevent excessive distortion.

**MANGANESE AUSTENITIC STEEL** with 12 to 14% Mn and approximately 1 to 1 1/2% C is quite brittle in the as-cast condition, because of large carbide areas, but upon heating to 1900° F. and quenching, the carbides are retained in solid solution and a tough ductile material results. On reheating to 1100 to 1400° F., carbides are again precipitated and the material becomes hard and brittle. In welding this steel it is necessary to deposit weld metal which is ductile and to avoid embrittlement of the base material by excessive heating.

Welding may be accomplished by either the gas or arc methods. A filler metal of 12 to 14% Mn and 3 to 5% Ni is recommended to obtain a good quality weld. Care should be taken to avoid excessive heating of the base metal.

**CAST IRON.**—Cast irons, either gray, white or malleable, are not considered adaptable to welding, but may be welded with proper care and procedure. White cast iron is the most easily welded. The process may be the gas or metal arc, using a white cast-iron filler rod. Resistance welding may be used where shape permits. Gray or malleable castings may be fusion welded with proper precautions, and the same general procedure can be applied for both types of castings. Whatever method is used, because of the low tensile strength and poor ductility of these materials, it is essential to avoid excessive variations in temperature throughout the casting to prevent cracking from thermal stresses.

**Gas Welding** is best performed by preheating the casting to approximately 1000° F. and completing the weld while the castings are hot. After welding, the casting must be cooled slowly. A suitable flux such as borax should be used, and the filler metal should be of a high-silicon cast-iron composition. Welds made in this manner will be machinable.

**Carbon Arc Welding** can be performed in a manner similar to that used for gas welding. Use of cast-iron filler rod and borax flux is recommended.

**Metallic Arc Welding** may be performed using either coated cast-iron composition electrodes or coated steel electrodes. Preheating is necessary in using the cast-iron electrodes, and this method will produce a machinable weld. The method is best adapted for welding in the flat position. Using coated steel electrodes, welds may be made without preheating the casting, but a hard unmachinable zone will be present. Small-diameter electrodes ($^1/_8$ in. maximum) should be used and welding should progress slowly with intermittent peening. This will keep thermal stresses in the casting, and contraction stresses in the weld metal, at a minimum. Welds made with steel electrodes will be considerably stronger than the cast-iron base metal. Welds not so strong, but very satisfactory and machinable, may be made, using an alloy electrode of high nickel composition such as Monel metal (68% Ni, 29% Cu). Similarly, welds may be made with copper or copper alloy filler metal.

## 5. SURFACING BY WELDING

For special applications, steels often are surfaced with another material in order to obtain resistance to wear or corrosion. These materials are conveniently welded to the steel base by gas or metal arc methods. For corrosion resistance, stainless steels or Monel metal commonly are used. For wear resistance or hard surface, deposits of plain high-carbon steels, alloy steels, high-speed steels, alloys of cobalt, chromium, and tungsten (Stellite), high-carbon austenitic steels such as Hadfield's manganese steel, and preparations of tungsten or boron carbides, are available. All of these materials may be applied by metal arc or oxygen-acetylene welding.

## 6. QUALIFICATION OF WELDERS

In all welding processes, but particularly in fusion welding processes such as gas welding and electric welding, employing manual welding, the quality of the welds for a given welding process depends largely on the skill of the welding operator. Weld quality depends less on the operator with automatic welding equipment. For manual welding by any of the processes, the welding operator should have received special training in making welds under conditions similar to those encountered on his production work. The skill of the welding operator should be checked from time to time. This generally is accomplished by what are known as qualification tests. The operator deposits a weld using the same process and under conditions similar to the production work which he is to undertake. Specimens from these qualification test plates are obtained and tested. Requirements for qualification tests of welding operators are quite varied as to detail. See Qualification of Welding Process and Testing of Welding Operators, *Jour.* Am. Welding Soc., 1936, Oct. Supplement.

# CORROSION OF METALS

By Frank N. Speller

## 1. CORROSION IN GENERAL

Corrosion of metals may be defined broadly as the chemical action of their environment, often resulting in their deterioration or destruction. Under most ordinary conditions of exposure the corrosion products comprise mainly oxides (more or less hydrated), carbonates, and sulphides. At high temperatures the products consist mainly of oxides, though indications are that corrosion of this type also progresses more rapidly when some moisture is present. Corrosion may be entirely superficial or may attack the intercrystalline boundaries and cause disintegration in the metal, as dezincification of brass or so-called caustic embrittlement in boiler steel.

It may be taken as established that in nearly all cases of corrosion at ordinary temperatures, comprising those most important in practice, the driving force of the corrosion reaction between metal and environment is electrochemical.

**ESTABLISHED FACTS REGARDING CORROSION.**—*a.* In most cases both moisture and oxygen are necessary for corrosion. *b.* The initial rate of corrosion usually is comparatively rapid, slowing as a protective film forms. *c.* Surface films are important in controlling the rate and distribution of corrosion. *d.* Increased rate of motion increases corrosion in water up to a certain velocity; the rate then may drop where strong protective films are formed. *e.* Dissimilar metals in electrical contact accelerate corrosion of the ones that happen to be anodic. Galvanic action is a most active agent of corrosion. It occurs when two metals, one electronegative to the other, are placed in contact and exposed to moisture. *f.* The composition of ordinary iron and steel has little or no effect on their relative rates of corrosion under water or under ground. Under these conditions the particular kind of metal usually is not so important as environment. *g.* Variation in the concentration of a solution in contact with a metal tends to localize corrosion. Where this is due to oxygen in solution, the surface to which the oxygen diffuses most rapidly is cathodic to the area that is protected from diffusion of oxygen. The smaller the anodic areas in relation to cathodic areas the greater is the rate of penetration at anodic points. Corrosion, like other chemical reactions, increases with temperature.

The above, and other facts (See F. N. Speller, Corrosion Causes and Prevention, McGraw-Hill Book Co., 1926), are the basis of the electrochemical mechanism which now is generally accepted to explain corrosion in the presence of water.

## 2. MECHANISM OF CORROSION

**CORROSION OF IRON OR STEEL IN GENERAL.**—While there is a vast difference in the amount of corrosion of iron and steel under different conditions, and while the relative corrosion varies with surrounding conditions, certain fundamental causes underlie all cases of corrosion.

Every metal when placed in water is subjected to a fixed tendency to go into solution. This is wholly a matter of electrochemical activity and varies to a definite extent with each metal. The initial reaction in the process of corrosion is analogous to solution in acid. The acidity of the water determines the initial speed of attack. As in all electrochemical reactions, however, the initial speed of solution soon slows down as the electrochemical couples which form over the surface of the metal become "polarized" due to the accumulation of hydrogen on their cathodic surfaces, ultimately stopping the solution of the metal. In the case of iron a small amount of the metal is dissolved as ferrous hydrate, which also retards the rate of solution of the metal. This first stage of corrosion of iron, while essential, is not serious if the reaction between water and iron can be stopped at this point. In fact, it cannot proceed unless, in some manner, the hydrogen film protecting the metal is removed. This is usually accomplished by some depolarizing agent, generally free oxygen, which also combines with ferrous hydrate forming insoluble ferric hydrate, commonly known as rust.

This second stage of corrosion, is thus caused by the oxidation of hydrogen and ferrous hydrate in solution by free oxygen from the atmosphere. Oxygen is soluble in water at normal temperature to the extent of about ten parts by weight per million, and as water readily absorbs more oxygen, the reaction will continue until the metal has been destroyed, or the reaction may be stopped by exhaustion of the available supply of oxygen. The latter case is illustrated in any closed water system, where in a metallic water pipe the amount of free oxygen will decrease as the water travels from the inlet. If, then, the pipe is long enough the corrosion will finally be reduced to a negligible amount.

Iron, like all other metals, when in contact with water or a solution has a definite inherent tendency to go into solution in the form of electrically-charged particles (iron-ions.). The solution must remain electrically neutral, and these positive ions can enter it only if an equivalent number of positive ions of some other elements are displaced. Thus, iron immersed in a solution of copper sulphate begins to go into solution, but simultaneously, an equivalent amount of copper is plated out on the surface of the iron, and protects it somewhat from further action. Similarly when iron is immersed in water, hydrogen is plated out and forms a thin invisible film on the iron surface.

**FACTORS CONTROLLING CORROSION.**—Primary factors are those having to do with the initial tendency toward solution, and are mainly associated with the metal itself. Secondary factors are those that influence the subsequent rate of corrosion, and usually are much more important than primary factors. They mainly depend on the environment of the metal. The main factors influencing corrosion are listed below, regardless of their relative importance which changes materially with environment.

**Primary Factors Having to Do Mainly with the Metal.**—1. Effective electrode potential of the metal in solution. 2. Chemical and physical homogeneity and texture of its surface. 3. Its inherent ability to form an insoluble protective film. 4. Overvoltage of hydrogen on the metal surface.

**Factors Which Vary with Environment.**—5. Hydrogen-ion concentration ($p$H) in the solution. 6. Effective supply of oxygen in the solution adjacent to the metal. 7. Distribution of available oxygen on the metal surface. 8. Specific nature, concentration, and distribution of other ions in the solution. 9. Effective rate of flow of the liquid past the metal surface. 10. Presence of solid particles (dirt), or a coating of any kind, as mill scale, on the metal surface, or contact with other conducting material in the presence of an electrolyte. 11. Temperature. 12. Whether the metal is under static stress conditions or exposed to cycles of alternating stress (the so-called corrosion fatigue). 13. The ability of environment to build up protective films on the metal.

While all the above factors are important under some conditions, the following deserve special attention and should be more clearly recognized:

**Oxygen.**—In most cases, oxygen concentration and the rate at which oxygen diffuses to the metal are controlling factors when the metal is immersed in water or buried in soil. The part to which the oxygen diffuses most readily is cathodic to the adjacent areas that are shielded by protective coatings or other material. That is, the points that are less accessible to oxygen corrode more rapidly than areas to which the oxygen has freer access. This and the galvanic effect from contact between dissimilar materials generally causes local corrosion or pitting.

**Surface Films.**—Clean metallic surfaces exposed to air quickly acquire a film of oxide, which at ordinary temperature is thin and invisible. At higher temperatures, it is thick enough to give well-known characteristic colors, varying with the temperature. The nature and properties of the film depend on the composition of the metal itself and its environment. Aluminum and stainless steels, for instance, owe their high durability, in certain environment, to the formation of a continuous and permanent film that is stable under the conditions of exposure. In other environment the film may not form, or is quickly dissolved. The metal, therefore, has short life under such conditions. The addition of 0.25% copper to ordinary steel increases the life of the steel in atmosphere two to four times, due to the formation of a dense adherent film apparently consisting of iron oxide with a little copper oxide on the surface of the metal. When copper steel is immersed in water or buried in soil, the protective film does not form. Under such conditions, copper steel has been no more durable than ordinary steel without copper.

If the metal has no inherent power to form a protective film in solution, a film may be built up by adding film-forming reagents, as the chromates or alkalies, to the water. When removed from the solution, however, these films are only temporary. To secure permanent protection it is necessary to maintain in the water the proper concentration of chromate, or other material, used for this purpose. Films, when formed, should be self healing, so that if injured or removed in any way, a new film will form immediately. Chromium will form a very resistant invisible film under oxidizing conditions, but in dilute hydrochloric acid, where such films cannot exist, chromium dissolves even more rapidly than pure iron. Metals which acquire a stable film by contact with an oxidizing solution are termed passive. In this condition they are at least temporarily resistant to corrosion when removed from the film-forming solution. The presence of thin invisible oxide films on passive material has been determined by the change in potential of the metal and by the removal of the films from the surface by selective dissolution of the underlying metal. See U. R. Evans, Thin Films in Relation to Corrosion Problems, *Jour.* Inst. Metals, 46, 7–23, 1931. Where the corrosion products form spongy layers of irregular thickness, they do not protect, and may even accelerate the normal action by interfering with the rate of diffusion of oxygen to the surface of the metal.

**Corrosion Fatigue.**—Metals subjected to repeated application of stress fail at considerably below their static ultimate tensile strength. However, the metal may be cyclically stressed indefinitely without apparent injury, below the so-called fatigue or endurance limit. This endurance limit is about one-half the tensile strength in the case of carbon steels. Even a small amount of corrosion present with cyclic stress will reduce considerably this endurance limit. Concentrated stress tends to accelerate the rate of corrosion. A notch is soon formed at the point of maximum stress and after this reaches a certain depth, the metal under cyclic stress fails by ordinary fatigue. The combined action of stress and corrosion is termed *corrosion fatigue.* The amount of cyclic stress that a metal will stand under these conditions depends on the character of the corrosion and on the nature of the protective films formed by the metal or its environment. Hence, it is difficult to conceive of a fixed corrosion fatigue limit for any metal under all conditions of exposure. Corrosion factors predominate in corrosion fatigue. Therefore, if there is a so-called corrosion fatigue limit, it usually is independent of the tensile strength. Heat treatment of steel raises the tensile strength and the air endurance limit, but if it does not increase resistance to corrosion it will have no material influence on the resistance to corrosion fatigue. Even 18% chromium steel and 18–8% chromium-nickel steels show a considerable reduction in endurance limit in corrosive environment. Carbon steels in the as-rolled condition may fail at less than one-half of their air-endurance limit when kept continuously wet, depending on the composition of the water and the amount of oxygen present.

An exceedingly small amount of corrosion is sufficient to depress the endurance limit of the metal under stress. In practice, therefore, it is important to prevent contact between stressed portions of metal and corrosive solutions. When inhibitors have been added to water that ordinarily causes failure at a relatively low stress by corrosion fatigue, the endurance of the steel has been maintained at the same stress as in dry air. This apparently is due to the formation and maintenance of a protective film on the surface of the metal under stress. See D. J. McAdam, Stress-Strain Cycle Relationship and Corrosion Fatigue of Metals, *Proc.*, A.S.T.M., Vol. 26, Pt. II, pp. 224–254, 1926; Corrosion Fatigue of Non-ferrous Metals, *Proc.* A.S.T.M., Vol. 27, Pt. II, p. 102, 1927; Some Factors Involved in Corrosion and Corrosion-Fatigue of Metals, *Proc.* A.S.T.M., Vol. 28, Pt. II, pp. 117–158, 1928; and Stress Corrosion of Metals, presented at the Convention of the New International Assoc. for the Testing of Materials, Zurich, Switzerland, 1931; also F. N. Speller, I. B. McCorkle, and P. F. Mumma, Influence of Corrosion Accelerators and Inhibitors on Fatigue of Ferrous Metals, *Proc.* A.S.T.M., Vol. 28, Pt. II, pp. 159–167, 1928.

**ELECTROLYTIC CORROSION DUE TO OVERSTRAIN.**—(C. F. Burgess, *El. Rev.*, Sept. 19, 1908).—Mild steel bars overstrained in their middle portion were subjected to corrosion by suspension in dilute hydrochloric acid solutions, and others by making them the anode in neutral solutions of ammonium chloride and causing current to flow under low current density. In all cases a marked difference was noted in the rate at which the strained portions corroded as compared with the unstrained. Differences of potential of from five to nine millivolts were noted between two electrodes, one of which constituted the strained portion and one the unstrained. The more rapid electrolytic corrosion of the strained portion appears to be due to the fact that the strained metal is electro-positive to the unstrained, the current finding the easier path through the surface of the electro-positive metal. That the strained metal is the more electro-positive is also shown by a liberation of hydrogen bubbles on the unstrained portion.

**EFFECT OF CORROSION ON WROUGHT MANGANESE BRONZE UNDER TENSILE STRESS.** (Paul D. Merica and R. W. Woodward, *Proc.* A.S.T.M., Vol. 19, 1919).—An investigation to determine what service stresses may, with safety, be applied to physically normal wrought brass and bronze showed that brass rods exposed to the action of concentrated ammonium hydroxide and subject at the same time to a gradual application of tensile stress, would break with little elongation at any values of the stress greater than the yield point of the material. It appears that the effect of combined tensile stress and surface corrosion is to decrease the stress at which fracture will occur. This discovery is important in that brass and bronze are substituted for steel usually only on account of their supposed superior resistance to corrosion. If this superior resistance is not as great as has been assumed, the field of brass and bronze for structural purposes is largely limited. The general conclusion seems to be that brass or bronze should not be subject to corrosion in ammonium hydroxide while under a tensile stress greater than 20,000 lb. per sq. in. or more than 5000 lb. per sq. in. above the yield point without danger of failure. The tests indicate that the proportional limit is to be regarded as the maximum safe stress for manganese bronze of harder tempers but it is not certain that this limit may not be slightly exceeded in materials that are soft; *i.e.*, free from work hardness.

## 3. PRINCIPLES OF TESTING

**RELATIVE CORROSION.**—Difference of opinion regarding the relative corrosion of iron and steel and other metals apparently is due to failure to appreciate that different factors control in different environments. Factors external to the metal usually determine the corrosion rate, and these vary considerably with environment. The relative rate, therefore, may vary under different conditions of exposure. This should be the basis on which all corrosion tests (laboratory or service) are designed. Thus, in a study of metals, under atmospheric conditions, the dominant factor should be an excess of oxygen. If the endurance limit of metal under water is in question, the test should be made in that environment alone. It is a mistake to take the results of tests made under one type of corrosion, *i.e.*, in the atmosphere or in acids, and to apply the conclusions to the conditions in which entirely different factors control. An extreme instance is the well-known acid test made by exposing the metals to dilute sulphuric acid, in regard to which the A.S.T.M. has issued the following statement:

> The continued functioning during the past 25 years of the Committee on Corrosion of Iron and Steel of the A.S.T.M. has developed no further information as to the relation of the accelerated acid test to corrosion by the elements, or the trustworthiness of the acid test as a measure of natural corrosion.
>
> Studies have been made to determine whether consistent results can be obtained in testing iron and steel sheets in 20% sulphuric acid, and if the results in acid compare favorably with the results of corrosion tests in the atmosphere. See Report on Total Immersion Tests, *Proc.* A.S.T.M., Vol. 31, Part I, p. 176, 1931.
>
> A representative average set of samples from two sheets each of ten materials of iron and steel, both copper bearing and non-copper bearing, part of each sheet having been exposed to the atmosphere, was tested by five co-operating laboratories following an exact accelerated acid test procedure. The life in acid of similar sheets in atmospheric corrosion tests at Pittsburgh, Pa., and Key West, Fla., indicated that an acid test conducted by the procedure followed by the committee is not capable of consistent repetition. Further, the data from such an acid test should not be used to forecast the relative life of ordinary ferrous materials in the atmosphere.

Clearly, the subject of relative corrosion should be studied on the basis of type of service. The service test is the final criterion of the value of the metal, although judiciously made laboratory tests, with proper consideration given to the factors involved, will show under accelerated conditions a fair approximation of results in service. Three common types of service to be considered are atmospheric, water and soil corrosion.

**ATMOSPHERIC CORROSION.**—In atmospheric corrosion, oxygen is the dominant factor. In general, results of tests indicate little difference between the various kinds of iron and steel except where copper is present in excess of 0.07%. With copper content of from 0.2 to 0.5%, the durability of steel in air is two to four times that of steel without copper. Fig. 1 shows the influence of copper on corrosion. The greatest contrast between copper steel and non-copper steel is found in industrial atmospheres. Wrought iron without copper shows slightly longer life than non-copper steel under outdoor conditions. This probably is due to the better adherence of the products of corrosion to the rough surface of the metal. Sulphur in excess of 0.06% tends to increase the rate of corrosion in industrial air. For results of authoritative work on this type of corrosion, see reports of Committee A-5 in *Proc.* A.S.T.M. dating from 1915 to the present time.

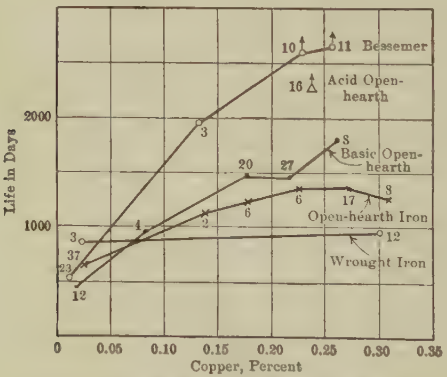

Fig. 1. Influence of Copper on Corrosion

A critical study of A.S.T.M. tests (V. V. Kendall and E. S. Taylerson, A Critical Study of the A.S.T.M. Corrosion Data on Uncoated Commercial Iron and Steel Sheets, *Proc.* A.S.T.M., Vol. 29, Pt. II, pp. 204–219, 1929), is summarized as follows:

> A study of the Pittsburgh and Fort Sheridan results confirms previous conclusions as to the

effect of copper. At the close of eleven years of observations of these tests, the sub-committee would direct attention to the fact that failures at the Fort Sheridan location confirm the findings at the Pittsburgh location, that copper-bearing metal shows marked superiority in rust-resisting properties as compared to non-copper bearing metal of substantially the same general composition under atmospheric exposure. (Report of Committee A-5 on Corrosion of Iron and Steel, *Proc.* A.S.T.M., Vol. 28, Pt. I, p. 156, 1928.) This paper also points out that at the Pittsburgh location, phosphorus combined with copper has beneficial effects from an atmospheric corrosion standpoint. Manganese and sulphur, within the limits of composition involved, seem to have little, if any, effect either way. The Fort Sheridan data, although limited on account of the incompleteness of the test, show similar beneficial results for high-copper material. The A.S.T.M. total immersion tests have been thoroughly studied, and, contrary to the atmospheric tests, the results indicate that the variation of the common elements, either singly or in combination, within range of composition and under the conditions of these tests, has no material influence on corrosion resistance and is entirely secondary to external conditions.

**Tests of Vent Lines** on the roofs of buildings were carried out by the National Tube Co., with wrought-iron, steel, and copper-steel pipe. Results based on the decrease in wall thickness indicated the relative loss of these metals to be as follows, taking steel as 100: wrought-iron, 92%, copper-steel, 36%.

**Tests on Hopper and Gondola Cars,** constructed one-half of copper steel and the other half of plain steel, showed after 13 years that the copper steel had about 200% longer life in the hopper cars (subjected to some abrasion with corrosion), and 300% longer life for the side sheets of the gondolas (subject to corrosion only) in comparison with plain steel of the same composition. The number of cars tested was 100. U. S. Unger (Results of Using Copper Bearing Steel in Freight Cars, *Rwy. Age*, Vol. 84, p. 1062, May, 1928), summarizes the experience with these cars as follows:

1. Paint adheres much better to copper-bearing steel in a car body than to plain open-hearth steel. 2. The saving in repainting cars, due to better adherence of paint to copper-bearing steel, would be sufficient to justify the use of copper-bearing steel in the bodies of steel freight cars. 3. Where mechanical abrasion has not been a serious factor, as in the side sheets of gondolas, the loss in thickness for the copper-bearing steel was only one-third as great as for the plain open-hearth steel. 4. Where the steel was subjected to severe mechanical abrasion as well as corrosion, the loss in thickness for the copper-bearing steel was approximately 60% as great as for the plain open-hearth steel. 5. From the results of this investigation, it can be conservatively stated that the use of all copper-bearing steel in the body of the cars would increase the life of the car body from 33 1/3 to 50%.

**Service Tests on Copper Steel Tie Plates,** containing 0.25% Cu, over a period of 11 years, show 5% loss in weight for copper steel and 20% loss for plain steel. Similar results have been obtained on cut spikes. See Report of Committee on Iron and Steel Structures, Am. Ry. Engrs. Assoc., *Rwy. Age*, Vol. 86, 562 pp. 166–167, 1929. Tests of 730 plain and a similar number of copper steel ties, in track for 9 years, indicate at least double the life for copper steel ties with a sub-grade of broken slag and ashes for ballast. See J. S. Unger, Comparison of Corrosion Resistance of Copper Steel and Plain Steel Railroad Ties, *Steel Maker*, Vol. 2, No. 1, pp. 93–95, Summer 1931.

**WATER CORROSION.**—When material is in continuous contact with water, the available oxygen is limited to its solubility in water. This affects the nature of the film formed by corrosion products, and therefore the rate of corrosion. Immersion tests were made by A.S.T.M. on the materials referred to above, in their atmospheric tests. The results show no material difference between the copper steels and similar steels without copper. Wrought-iron, steel and ferrous alloys commonly used in the manufacture of pipe, tested in service in warm water and return steam pipe lines, show the results given in Table 1. They are summarized according to condition of service and material in Table 2. In connection with these tables the following should be noted: 1. Tests are arranged in chronological order, 1910 to 1931. 2. Table 1 covers the results of 57 tests expressed in terms of measured pitting. 3. Table 2 is a classification of the tests listed in Table 1, based on character of service and material, and gives 78 comparisons of other ferrous material against steel. 4. For convenience, wherever possible, the amount of corrosion also has been figured in percentage, the corrosion being taken as 100.

Examination of these test samples from various parts of the country indicate no fundamental difference in the rate of corrosion of any of the materials *in water*, except that the copper steels are somewhat more durable for return steam lines, where corrosion at times is of the wet and dry type as in air. For further information and practical experience with steel pipe for water service, see H. R. Redington, J. L. W. Birkinbine, F. N. Speller, Corrosion of Water Mains, *Jour.* A.W.W.A., Vol. 23, No. 11, Nov. 1931.

**SOIL CORROSION.**—Under ground, the dominant factor is local electrolytic action, resulting in pitting. The rate of penetration varies with moisture content, electrical resistivity, physical structure and chemical composition of the soil and ground water, and stray electric currents leaving the pipe (electrolysis).

(*Continued on p.* 3-11)

**Table 1.—Summary of Complete Record of Comparative Service Corrosion Tests of Pipe**

Tests conducted in co-operation with outside interests by Dept. of Metallurgy and Research, National Tube Co., Pittsburgh, Pa. For significance of symbols in Tables 1 and 2, see Notes A, B and C, p. 3–10.

† The figures in these tests are grand averages for penetration of corrosion in inch per year, based either on weight lost or decrease in wall.

(*Continued from page* 3–07)

The U. S. Bureau of Standards has conducted an extensive investigation of steel corrosion from 1924 in typical soils in the U. S. This comprehensive test includes some 15,000 samples. For detailed records of the tests, see Research Papers Nos. 95 and 329, U. S. Bureau of Standards. A summary of the weighted average results, based on maximum pits on ferrous metals from all soils included in these tests over a period of eight years, is given in Fig. 2.

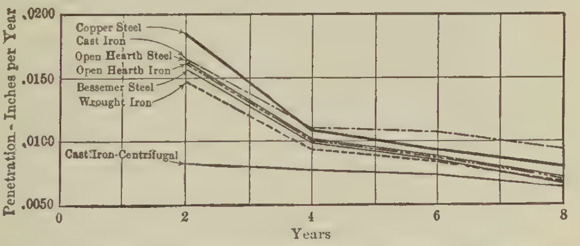

Fig. 2. Results of Bureau Standards Soil Corrosion Investigation

**CHEMICAL CORROSION** includes the action of acids and other chemicals. It is only possible to determine the relative durability of ferrous materials under such variable conditions by actual tests, in each case, in the laboratory, or preferably in service.

## 4. PREVENTION OF CORROSION

Deterioration of metals may be prevented or reduced in three ways: 1. By using a more resistant metal. 2. By application of a suitable protective coating. 3. By making the environment less corrosive. The amount of protection specifically depends on the corrosive nature of the environment and must be chosen to suit the conditions and with a view to economy.

**Protection Against Atmospheric Corrosion.**—A large variety of paints, lacquers, and similar protective materials has been developed, which cannot be summarized here. See publications of American Paint and Varnish Mfrs. Assoc., distributed by the Institute of Paint and Varnish Research Laboratory, Washington, D. C. Many products suitable for atmospheric protection have been developed in the past few years, some being decidedly superior to the old type of linseed oil paints. These are mostly compounds of synthetic resins, applied with or without baking, self-curing rubber compounds, and the nitrocellulose lacquers. See H. A. Gardner, Physical and Chemical Examination of Paints, Varnishes, Lacquers, and Colors; Report of Inst. of Paint and Varnish Research, Oct. 1930.

## Paints and Varnishes

**References.**—Technology of Paint and Varnish, A. H. Sabin (John Wiley & Sons): Reports of Committee, D-1, Am. Soc. Test. Mat.; Modern Pigments and Their Vehicles, Maire (John Wiley & Sons).

**PAINT.**—Composed of a vehicle or binder, usually linseed oil with some tung oil, or varnish (enamel paints), and a pigment, which is a more or less inert solid in the form of a powder, either mixed or ground together. Nearly all paint contains paint drier or japan, which is a lead or (and) manganese compound soluble in oil, and acts as a carrier of oxygen; as little should be used as possible. Boiled oil contains drier; no additional drier is needed. None should be used with varnish paints, nor with "ready-mixed paints" in general.

The principal pigments are white lead (carbonate or oxy-sulphate) and white zinc (oxide), red lead (peroxide), oxides of iron, hydrated and anhydrous, graphite, lampblack, bone black, chrome yellow, chrome green, ultramarine and Prussian blue, and various tinting colors. White lead has the greatest body or opacity of white pigments; three coats of it equal five of white zinc; zinc is more brilliant and permanent, but it is liable to peel, and it is customary to mix the two. These are the standard white paints for all uses, and the basis of all light-colored paints. Anhydrous iron oxides are brown and purplish-brown, hydrated oxides are yellowish-red to reddish-yellow, with more or less brown; most iron oxides are mixtures of both sorts, and often contain a little manganese and much clay. They are cheap, and are serviceable paints on wood and are often used on iron, but for the latter use are falling into disrepute. Graphite used for painting iron contains from 10 to 90% foreign matter, usually silicates. It is very opaque, hence has great covering power and may be applied in a very thin coat, which is to be avoided. The best graphite paints give very good results. There are many grades of lampblack; the cheaper sorts contain oily matter and are especially hard to dry; all lampblack is slow to dry in oil. In a less degree this is true of all paints containing carbon, including graphite. Lampblack is used with advantage with red lead; it is also an ingredient of many "carbon" paints, the base of which is either bone black or artificial graphite. Red lead dries by uniting chemically with the oil to form a cement; it is heavy, and makes an expensive paint, and is often highly adulterated. Pure red lead has long had a high reputation as a paint for iron and steel, and is still used extensively, especially as a first coat; but of late years some of the new paints and varnish-like preparations have displaced it to a considerable extent, even on the most important work.

**VARNISHES** are made by melting fossil resin, to which is then added from half its weight to three times its weight of refined linseed oil, and the compound is thinned with turpentine; they usually contain a little drier. They are chiefly used on wood, being more durable and more brilliant than oil, and are often used over paint to preserve it. Asphaltum is sometimes substituted in part or in whole for the fossil resin, and in this way are made black varnishes which have been used on iron and steel with good results. Asphaltum and substances like it have also been simply dissolved in solvents, as benzine or carbon disulphide, and used for the same purpose.

All these preservative coatings are supposed to form impervious films, keeping out air and moisture; but in fact all are somewhat porous. On this account it is necessary to have a film of appreciable thickness, best formed by successive coats, so that the pores of one will be closed by the next. The pigment is used to give an agreeable color, to help fill the pores of the oil film, to make the paint harder, so that it will resist abrasion, and to make a thicker film. In varnishes these results are sought to be attained by the resin which is dissolved in the oil. There is no sort of agreement among practical men as to which coating is best for any particular case; this is probably because so much depends on the preparation of the surface and the care with which the coating is applied, and also because the conditions of exposure vary so greatly.

**APPLICATIONS.**—Cast-iron water pipes usually are coated by dipping in a hot mixture of coal-tar and coal-tar pitch; riveted or welded steel pipes by dipping in hot asphalt. Ships' bottoms are coated with a red lead or other inhibitive primer and a varnish paint to prevent rusting. Over this is a second coat containing a poison, as mercury chloride or a copper compound, or a greasy copper soap applied hot; these tend to prevent the accumulation of marine growths. Galvanized iron and tin surfaces should be thoroughly cleaned with benzine and scrubbed before painting. When new, they are partly covered with grease and chemicals. These must be removed or paint will not adhere. Weathering for six months prior to painting serves the same purpose in preparing galvanized steel surfaces.

## 5. CORROSION-RESISTING PROCESSES

**CEMENT.**—Iron-work often is bedded in concrete; if free from cracks and voids it is an efficient protection. The metal should be cleaned and then washed with neat cement before embedding.

**BOWER-BARFF PROCESS.**—Dr. Barff's method was to heat articles to be coated to about 1800° F. and inject steam heated to 1000° F. into the muffle. George and A. S. Bower used air instead of steam, then carbon monoxide (producer gas) to reduce the red oxide. In the combined process, the articles are heated to 1600° F. in a closed retort; superheated steam is injected for 20 min., then producer gas for 15 to 25 min.; the treatment can be repeated to increase the depth of oxidation. Less heat is required for wrought- than for cast-iron or steel. By a later improvement, steam heated above the temperature of the articles was injected during the last one to two hours. By a further improvement known as the Wells Process, the work is finished in one operation, the steam and producer-gas being injected together. Articles are slightly increased in size by the treatment. The surface is gray, changing to black when oiled; it will chip off if too thin; it will take paint or enamel and may be polished, but cannot be either bent or machined; the coating itself is incorrodible and resists sea-water, mine-water and acid fumes; the strength of the metal is slightly reduced. The process is extensively used for small hardware. (See F. S. Barff, *Jour.* I. & S. Inst., 1877, p. 356; A. S. Bower, *Trans.* A.I.M.E., 1882, p. 329; B. H. Thwaite, *Proc.* Inst. C. E., 1883, p. 255; George W. Maynard, *Trans.* A.S.M.E., iv, p. 315, 1883.)

**RUSSIA AND PLANISHED IRON.**—Russia iron is made by cementation and slight oxidation. W. Dewees Wood (U. S. Pat. No. 252,166 of 1882) treated planished sheets with hydrocarbon vapors or gas and superheated steam within an air-tight and heated chamber.

**NITER PROCESS.**—An old process improved by Col. A. R. Buffington in 1884. The articles are stirred about in a half-and-half mixture of fused sodium and potassium nitrate (saltpeter) to which is added manganese dioxide in the ratio of 1 part oxide to 50 parts niter by volume. They then are suspended in the vapors, dipped and washed in boiling water and finally immersed in hot oil. Pure chemicals are essential. Used for small arms and pieces which cannot stand the high heat of other processes. The temperature of the bath should be from 600 to 650° F. to yield a temper blue, and 1000° F. to yield the dark gun-metal finish used for rifle parts.

**PHOSPHATIC COATINGS FOR RUST-PROOFING IRON AND STEEL.** (L. E. Eckelmann, *Chem. & Met. Engg.*, Dec. 24, 1919).—Recent phosphatic rust-proofing differs from other methods in that the dimensions, sharpness of edges of the articles are not altered, and the physical properties of tempered steel are not affected. Rust-proofing is effected by immersing the clean objects in a hot solution of iron phosphates in weak $H_3PO_4$. Phosphoric acid solutions will dissolve ferrous phosphate within certain limits in direct proportion to the concentration of the acid present. If any base or metal, as iron, be added—capable of combining with the free acid in such a solution, ferrous phosphate forming on the metallic surfaces will precipitate this salt back on the iron at the point of solution. The action proceeds with the evolution of hydrogen until no more iron is exposed, the article being then completely coated with a basic iron phosphate.

**Coslett Process.**—The foregoing reaction was the basis of the process developed by Coslett in 1907, in which ferrous phosphate, made by mixing iron filings with concentrated $H_3PO_4$ sufficient to form a semi-fluid paste was added to weak boiling phosphoric acid. Iron or steel articles immersed in this solution, for three or four hours, become covered with a rust-resisting light gray deposit of basic ferrous phosphate. The difficulty of obtaining uniform coatings, the great amount of suspended salt adhering to the work, the necessity of rinsing work after treatment, and the non-uniformity of the finish, made the adoption of this process slow.

**Parkerizing** is the process by which a coating of insoluble phosphates is produced on the surface of iron, using a bath containing some free phosphoric acid and a mixture of ferrous monohydrogen phosphate and manganese dihydrogen phosphate. The coating produced is less than 0.0002 in. thick and has maximum rust-resisting ability when the ratio of iron to manganese in the coating is 1 : 1. The free phosphoric acid is produced by the hydrolysis on boiling of ferrous dihydrogen orthophosphate. The bath is maintained at 208–210° F. The ratio of iron to manganese in the bath is 2 : 1. About one hour is required. A small amount of copper phosphate can be added as an accelerator to speed up the reaction and reduce the time required to 10 minutes. The resultant coating forms an excellent base for paints, lacquers, and organic enamels. It can be electroplated either before or after buffing. The coating is not as rust-resistant as the one obtained from the plain phosphate bath but its value can be greatly enhanced by stoving or by short immersion in a hot chromate solution.

**Bonderizing** is the term used when the preliminary accelerated phosphate treatment is applied to act as a base for paints or lacquers. It is claimed that should the surface be scratched or injured during subsequent service, rust cannot spread beneath the Bonderizing coating.

**GALVANIZING** is a method of coating steel or iron articles with zinc, the product being known as galvanized steel or iron. Galvanized coatings usually resist, for a reasonable time, ordinary corrosive conditions such as in fairly pure air, moderately hard domestic waters, sea water, brines, etc. The zinc, particularly under atmospheric conditions, often becomes hardened with a protective layer or film believed to be a zinc-hydroxide-carbonate mixture. Zinc is anodic to iron and therefore protects the base metal, where exposed, until the adjacent outer layer of zinc is dissolved. Galvanized coatings are unsuitable where the corroding agent is very acid, as in certain mine waters and industrial solutions, or where the solutions are excessively alkaline, *e.g.*, calcium brines with an excess of caustic alkalinity. Favorable $p$H values are given between 5 and 8.5 and temperatures below 160° F. In brines the $p$H should not exceed 8. Very hot soft water attacks galvanizing.

Galvanized coatings are commercially applied: *a*, by dipping the article in molten zinc; *b*, by electroplating; *c*, by heating in contact with zinc powder.

**Hot-dip Galvanizing.**—Articles to be hot-dipped galvanized usually are cleaned by acid pickling, washed, and fluxed by immersion in a bath of zinc ammonium chloride or hydrochloric acid. They then are dipped in molten zinc maintained at 830 to 920° F. When the steel has reached approximately the zinc temperature, requiring a few seconds in the case of wire and several minutes for heavier sections, it is drawn slowly from the bath, allowing time for draining. In the case of wire, excess zinc often is removed and the coating smoothed mechanically by asbestos or charcoal wipers. Long, slightly corrugated rolls are similarly used for sheets. The article may cool in air, producing a spangled (crystalline) zinc surface, or it may cool rapidly in water, producing a matte surface.

Adherence of zinc coatings depends on the formation of suitable zinc-iron alloys. Some grades of wire and sheets, conduit pipe, etc., requiring maximum bending qualities are made with light coatings consisting largely of zinc-iron alloy formed by wiping after dipping. Where bending requirements are secondary, and maximum corrosion resistance is desired, as for other grades of iron and sheets, galvanized water pipe, galvanized ware, etc., the galvanizing should be considerably heavier, and with more pure zinc in the coating. The average weight of coating applied varies from $^1/_2$ to 2 $^1/_2$ oz. per sq. ft. of covered surface, depending on the thickness of base metal, temperature and time in bath, and amount of wiping.

In the process of galvanizing, tin is at times added to the zinc bath to improve the spangle, while aluminum may be added to improve the fluidity of the bath and brightness and smoothness of the coating. The vapor of burning sulphur or ammonium chloride dust on the zinc surface as it comes from the bath has been used to improve brightness.

**Electrogalvanizing.**—Electrogalvanized zinc coatings are applied to conduit pipe, wire and intricate shapes. Electrogalvanized coatings on the threads of pipe couplings prevent sticking or galling of the threaded joints, and generally are used for tubular goods in petroleum production. Articles to be electrogalvanized may be cleaned by pickling with or without the aid of electric current, or machined surfaces may be cleaned with alkaline grease removers. The zinc is deposited from sulphate or cyanide baths using low-voltage plating current.

**GALVANIZING BY CEMENTATION. SHERARDIZING.** (H. A. Calderwood, Natl. Elec. Prod. Corp.).—The characteristic feature of the cementation process, sherardizing with zinc being a well-known example, is a definite and appreciable alloying of the surface of the treated metal. The treatment does not result in a layer of the simple secondary metal adhering to the base metal, but in an alloy of the two metals which varies in richness, there being more of the secondary metal at the surface of the coating.

Cementation, such as sherardizing, involves the use of the coating or cementing metal in the form of fine powder. The articles to be treated are placed in a drum or retort, which then is nearly filled with the metal powder, sealed and brought to the proper temperature. This temperature is in some cases well below the melting point of the cementing metal, in others, close to or slightly above its melting point, depending upon the metals involved, the character and texture of surface finish desired, and other considerations such as required speed of operation.

Sherard Cowper-Cowles (England) refined and perfected the process of cementation with zinc, and British and U. S. patents were granted to him in 1902 for the method known as Sherardizing. It consists in packing the articles to be sherardized, usually steel, in a retort with zinc powder known as *blue dust*. The retort or drum is tightly sealed, and by suitable means so heated that its contents attain a temperature approaching the melting point of zinc. The melting point of zinc is 786° F. and sherardizing usually is carried on at from 600 to 700° F., although it can be done at temperatures above or below this range. Better results are obtained if the drums are slowly rotated, and this generally is done in order to bring a fresh supply of dust into intimate contact with the articles being treated. The time required is from two to four hours. After drums are removed from the heating oven, they are allowed to cool before being opened. The time required for cooling is one to several hours, depending on the size of the retort. Prolonged heating and slow cooling of steel articles embedded in zinc dust, which is a poor conductor of heat, tends to soften them, which is highly desirable for objects which must be cut and bent.

**Blue Dust** is a natural by-product of smelting zinc, but when especially made of greater purity and uniformity for the purpose of sherardizing, is known as sherardizing zinc dust. It consists of minute particles of zinc metal, each encased in a thin skin, shell, or pellicle of zinc oxide. Commercial sherardizing zinc contains about 95 to 97% metallic zinc. The remainder is chiefly zinc oxide, with traces of impurities such as iron and lead. The resultant coating is a true zinc-iron alloy, ranging from $Fe\ Zn_3$ at the base metal line to $Fe\ Zn_{10}$ near the surface, and a layer of relatively pure zinc on the exterior; exact analysis naturally is difficult.

**Characteristics of a Sherardized Coating** are: *Color*, a rich gray; *texture*, which is matte, caused by innumerable minute fissures not visible to the unaided eye, and which has a velvety feel; *ability to receive and retain paints*, varnishes, enamels, etc., due to the bonding effect in the minute fissures; *uniform distribution and penetration*, making possible the effective coating of irregularly-shaped and hollow articles, screw threads, holes, etc., without building up on corners or actually filling up depressions, although allowance must be made for thickness on threads and other closely fitted parts: *ductility and tenacity*, which prevents flaking and slivering when sherardized articles such as pipes and sheets are bent; ability to take a high polish, the surface being relatively hard.

**Corrosion Resistance of Sherardizing.**—The principal object of metallic coatings being to prevent corrosion, performance of sherardizing in this respect is important. Concerning exposure to ordinary attacks indoors, and when exposed to weather and the zinc is oxidized, Rawdon (Protective Metallic Coatings, p. 112, Chem. Catalog, 1928) says:

> The coating gradually assumes a dark appearance as the iron likewise is oxidized, finally becoming a very dark gray and almost black if the iron content is not too high. Coatings high in iron, and hence containing the iron-rich compound, usually show a red dusty surface on weathering from the ferric oxide produced. A wrong impression often is formed concerning such coatings, that is, that the coating has been entirely corroded away and that the red dust indicates an exposure of the base metal. It can generally be shown that such is not the case.

When this color is not due to rusting of the base metal, the red or yellowish formation usually disappears in a short time, and the surface darkens. The black coating is believed to be the magnetic oxide of iron. When sherardizing acquires this surface formation it becomes highly resistant to further corrosion. The relation of thickness of coating to durability is important, since a heavy coating is, for mechanical reasons, objectionable on some articles, particularly those subject to bending and flexing.

Opinions differ regarding the mechanism of the sherardizing (cementation) process. Rawdon says:

> All agree that once the zinc is deposited on the surface of the iron article embedded in the zinc dust, alloying results by diffusion in the solid state. The method by which the zinc is deposited on the surface is the disputed point. Some (A. Sange, *Electrochem. and Metal. Ind.*, Vol. 7, p. 485; L. McCulloch, Factors Influencing the Process of Sherardizing, *Elec. Jour.*, Vol. 19, p. 156, *Trans.* A.I.M. & M.E., Vol. 68, p. 757) consider that the slight vaporization of the zinc which occurs even at the relatively low temperature used in this process is sufficient to account for the transportation of the zinc from the dust particles to the iron surface. Others (J. W. Hinchley, Some Practical Experience of the Sherardizing Process, *Trans.* Faraday Soc., Vol. 6, p. 133, and O. W. Storey, The Sherardizing Process, *Met. and Chem. Engg.*, Vol. 14, p. 683) hold that intimate contact of the zinc particles and iron surface is sufficient, and that the zinc particles become attached bodily to the surface. The discussion is one of academic rather than practical interest. Both factors undoubtedly contribute to the coating process as carried out in practice.

**TESTS AND SPECIFICATIONS FOR GALVANIZED COATINGS.**—Galvanized coatings usually are specified as a given weight of zinc per unit area. If bending or forming is anticipated, bend tests may be specified. Coatings may be expressed as ounces of zinc per square foot of surface, and determined by weighing a suitable sample of the galvanized article, removing the zinc, and reweighing. The usual means of removing the zinc is hydrochloric acid containing sufficient antimony chloride to prevent attack on the base metal. The minimum thickness of galvanized coatings, particularly on wire, also is expressed in terms of the Preece test, which consists of dipping the zinc coated article in a neutral solution of copper sulphate (sp. gr. 1.186 at 18° C.) for periods of one minute, washing and wiping between each dip until the zinc is penetrated, as shown by the formation of adherent copper on the exposed surface of the steel. Coating weight is expressed as number of dips to cause failure For details of both methods, see Standard Methods of Determining Weight of Coating on Zinc Coated Articles, A.S.T.M. Specification, Designation A 90–30.

Specifications for most commercial products covering weight of coating and bend tests when required are available in A.S.T.M. Standards, 1936, Part 1, Metals.

On sheets, coating weights are given as weight per sq. ft. of sheet, *i.e.*, 2 sq. ft. of coated surface. Ordinary coatings on sheets range from 1.25 to 2.75 oz. per sq. ft. of sheet coated on both sides. The weight of zinc per single covered surface would be one-half this amount. Zinc coatings on pipe, structural shapes, etc., generally range between 1.5 and 3.0 oz. per sq. ft. of covered surface. The weight of coating on wire varies with the size of wire and process of coating, and, except in fine sizes, will range from 0.15 to 1.25 oz. per sq. ft. of covered surface.

**LEAD COATINGS.**—Lead is very resistant to some types of corrosion, and lead coatings on steel have been used to some extent. A thin coating of lead, however, is difficult to apply, either by electroplating or hot dipping, so as to be sufficiently free from pin holes to be effective when submerged in corrosive water. The atmospheric resistance of such coatings usually is quite good. Hot-dipped lead sheets, known as terne plate, are extensively used. Wrought steel or iron pipes protected on the interior by thick lead tubes mechanically applied, when carefully installed with suitable fittings and valves, are effective for carrying corrosive acids and similar liquids.

**RUST-RESISTING METALS.**—**Iron.**—Various modifications of iron and steel have been introduced to give better service under atmospheric conditions. High purity iron and ingot iron (see p. 2–06) have considerable resistance to corrosion, but the purity of iron has been shown to be a minor factor in most types of natural corrosion, as external conditions usually predominate. This grade of iron is included in the A.S.T.M. corrosion tests referred to on p. 3–06.

**Copper Steel** has found a wide commercial application on account of its slow rusting properties under atmospheric and similar conditions of exposure. See D. M. Buck, A Review of the Development of Copper Steel, Year-Book Am. Iron and Steel Inst., pp. 373–379, 1920. Over 500,000 tons of copper steel in sheets, plates, and similar products have been manufactured for use where the metal is exposed to the weather. The addition of 0.25% copper at an increased price of $3.00 per ton usually will prolong the life of the metal two to four times under such conditions. (See also p. 3–06.)

**Corrosion-resistant Alloys,** containing high percentages of chromium are widely used. See pp. 3–19 to 3–24.

## 6. PROTECTION AGAINST UNDER WATER CORROSION

The main factors controlling the rate of corrosion in water are dissolved oxygen, temperature, rate of motion, and the composition of the water. The chemical composition of ferrous metals, within rather wide limits, does not seem to have a marked influence on the character or amount of corrosion. The high chromium series of steels are an exception to this. With cold water the rate of corrosion is usually slow, but in hot water the corrosive action is accelerated according to the temperature, the rate being doubled for every 25 deg. F. ± increase in temperature.

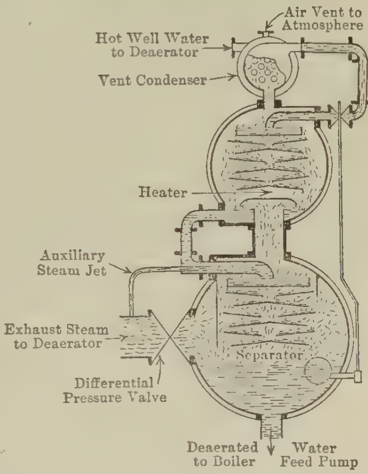
Localized corrosion or pitting usually is much deeper near mill scale, especially where the scale is thick and firmly adherent, undoubtedly due to the electro-negative character of the scale with respect to the iron. Old rust acts somewhat similarly but is less harmful. Removal of mill scale and rust greatly reduces the tendency to pitting, providing the metal itself is fairly homogeneous and free from strains. Surface finish is a greater controlling factor in corrosion than is the variation in the composition of the metal itself.

Within certain limits, corrosion varies directly with the temperature and the rate of flow and also with the composition of the water. Corrosion is likely to be more rapid on unprotected metal with increasing velocity of the water. The amount of corrosion is almost directly proportional to the amount of oxygen in the solution in the water. Hot water heating systems show practically no corrosion after 35 or 40 years of use, whereas hot water supply systems, operating at the same temperatures, have deteriorated in from 6 to 8 years. The only difference between the two is that the heating system carried no oxygen while the water in the supply system usually is saturated with it.

In some cases it is more economical to prevent internal corrosion by removing dissolved oxygen from the water, especially with hot water. Oxygen removal may be accomplished: 1. By mechanical deaeration for which there are two or three satisfactory designs of apparatus in use. 2. By the chemical combination of the oxygen with some material such as scrap and sheet iron. The two methods may be combined by using mechanical deaeration to remove most of the oxygen and chemical treatment for the remainder.

**MECHANICAL DEAERATING OF WATER** is accomplished by passing the water over baffles or spraying into a high-vacuum chamber at normal temperature, or by increasing the temperature and controlling the pressure and temperature so that more or less complete removal of all the gases is obtained. One system involves heating the water above the boiling point corresponding to the pressure and spraying it into a chamber at lower pressure. The air and aqueous vapor are drawn through a condenser where the vapor is condensed with a simultaneous transfer of heat to the incoming cold water.

For practical protection of water pipe from internal corrosion at 180° F., the oxygen need not be lower than 0.4 c.c. per liter (cold water carries from 5 to 10 c.c. per liter, depending on the season of the year and temperature). To avoid appreciable corrosion in steam boilers, superheaters and economizers operating at a much higher temperature, the oxygen should be below 0.03 c.c. per liter. This may be accomplished by means of deaerators now on the market.



Air Vent to Atmosphere
Hot Well Water to Deaerator
Vent Condenser
Heater
Auxiliary Steam Jet
Exhaust Steam to Deaerator
Separator
Differential Pressure Valve
Deaerated Water to Boiler
Feed Pump

Fig. 3. Principle of Deaerator

Fig. 3 shows diagrammatically a type of deaerator in which a current of steam sweeps over the surface of the heated water. The water and steam are brought to the same temperature, which facilitates complete removal of dissolved gases (mostly free O, $CO_2$ and N). After extracting the residual gases from the water, the steam flows upwards into the heater, and gives up its heat to the incoming water. Where conditions warrant complete recovery of the heat, a condenser cooled by the incoming water to the heater, may be installed at the vent. An auxiliary steam jet brings the temperature of water leaving the heater chamber to the temperature of the steam in the separator chamber. The cycles of operation are: Water from the supply line passes through the vent condenser, and, controlled by the float valve, enters the heating chamber, where it is heated to the desired temperature by steam previously used for deaeration. The heated water then flows through the piping between heater and separator, where it comes in contact with the auxiliary steam jet. This injects into the water sufficient steam to compensate for the temperature depression of the heater, and the water enters the separator or deaerating chamber, at substantially the temperature of the steam. It cascades over the trays and is agitated in the presence of the steam. The steam sweeps through the separating chamber, deaerates the water, and flows up through the steam passage between the separator and the heater. The water drops into the lower part of the separator, and is pumped to the boilers, economizers, or service line. The gases are vented into the vent condenser.

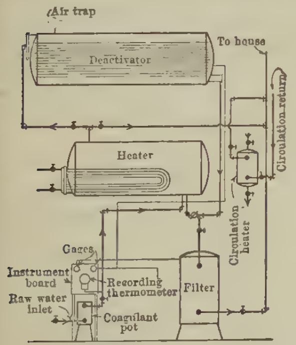


Fig. 4. Principle of Apparatus for Fixing Free Oxygen

**FIXING OF FREE OXYGEN IN WATER BY CHEMICAL COMBINATION** is effected in practice by passing heated water through a storage tank carrying a mass of expanded sheet iron, giving about 60 to 70 sq. ft. of surface per cu. ft. of space. At 170° F. the oxygen may be reduced in this way in about 1 hr. to 0.3 c.c. per liter. If, as is usual, the water carries free $CO_2$ and bicarbonates, the free $CO_2$ often is a little higher under this treatment, notwithstanding which, practically no corrosion is found. The first plant of considerable size based on this principle was built in Pittsburgh in 1915. The essential features are indicated in Fig. 4. For domestic use, the water must be filtered after treatment.

**COMBINATION OF MECHANICAL AND CHEMICAL DEAERATION.**—Deactivation (a term suggested to designate chemical deaeration process) may supplement mechanical deaeration. Such combination seems to be the most economical means for complete oxygen removal from hot water on a large scale under average conditions. Water so treated is practically inactive toward iron, and may be used in boilers or steel economizers without fear of corrosion.

Other metals in scrap form, as zinc, may be used for oxygen removal, but iron is the most economical, not only because of low first cost, but also because the residual ferrous hydrate formed renders the water slightly more alkaline. Sodium sulphite sometimes is used effectively for this purpose. In high pressure steam boiler practice, in addition to the complete removal of the oxygen, the water should be kept slightly alkaline with *p*H of about 9.

**CORROSION IN STEAM BOILERS.**—Internal corrosion may be caused by the use of water containing free acid, by water containing chloride of magnesium, which decomposes when heated, liberating acid, or by water containing air or carbonic acid in solution. External corrosion rarely takes place when a boiler is kept hot, but when cold it is apt to corrode rapidly in those portions where it joins the brickwork or where it may be covered by dust or ashes, or wherever dampness may lodge.

**CORROSION OF NON-FERROUS PIPES.**—The corrosion of brass, zinc, and other metals is greatly retarded or entirely stopped by removing oxygen from the water in contact with these metals. Brass and copper piping are sometimes seriously attacked by heated water under pressure. Water heated in a copper boiler of the usual type loses nearly one-half of its free oxygen in passing through the heater. Brass pipes after 10 or 12 years frequently have lost nearly all their zinc content. The same has been observed with alloy condenser tubes. It is now generally recognized that no one metal will meet all requirements of service. Ordinary brass pipe (30 Zn, 70 Cu) is adequate where the water is fairly pure and almost free from chlorides; red brass (15 Zn, 85 Cu) is much more durable where the water carries considerable amounts of soluble salts and is less likely to suffer dezincification. This grade is preferable for sea water. Copper pipe usually is more durable than brass for practically all domestic water service. See J. R. McDermot, Separation of Dissolved Gases from Water, *Trans.* A.S.M.E., xlii, p. 267, 1920. Also F. N. Speller, W. H. Walker, and R. G. Knowland, *Trans.* A.S.H.V.E., 1918–1920.

## 7. PROTECTION AGAINST SOIL CORROSION

**SOIL CORROSION** is highly localized and usually is caused by electrochemical action resulting from variations in the soil and solutions therein. Low alloy steels, *i.e.*, steels with less than 10% Cr do not show enough advantage, from an economic standpoint, under severe soil corrosion to warrant their use and the solution of the problem of longer life of underground pipe is practically limited to a selection of suitable protective coatings.

Soil corrosion varies considerably from point to point on pipe lines. On long lines serious damage is confined to 5% or less of the line as a rule. (W. T. Smith, Economy in Wider Use of Protective Coatings on Pipes, *Eng. News-Record*, April 21, 1932.) It, therefore, is advantageous to have a soil survey of the territory through which the pipe line will run, before deciding on the type of protective coating, if any, to be used. Much progress has been made in the study of soil factors at the U. S. Bureau of Standards, so that a careful survey, judiciously interpreted, with regard to all of the factors involved, should give an approximate idea as to the corrosivity of the soil. See U. S. Bureau of Standards Research Papers Nos. 95, 298, 329, 359, and 363. A survey, together with experience on pipe lines situated in similar soils, affords a fairly sound basis for selecting the most economical coating for a particular location.

**BITUMINOUS COATINGS** have been mostly used for underground protection. These consist of the well-known coal tar and asphalt dip coatings; preferably applied, after removing all grease, dirt, and loose mill scale, by vertically dipping the pipe in a bituminous bath at about 350° F. The melting point of the asphalt mixture should be varied between 140° and 190° to suit climatic conditions. Coatings of this type, properly applied at the mill, are suitable only for mild corrosive conditions, but afford good protection on the inside of water mains. In wet, marshy places, or in alkaline or acid soils, more substantial protection often is required. A thicker coating may be applied at the trench, but the pipe either should receive an asphalt or coal tar dip coating, or a coating of a suitable bituminous primer applied cold at the plant before shipment to prevent rusting in transit. Bituminous coatings usually are reinforced with fabric or with saturated felt wound spirally on the pipe over the dip coat. Asbestos-base reinforcement is preferable. In certain soils, unless these bituminous coatings have a high melting point and are unusually rigid, they are subject to soil stress; that is, some soils have a tendency to cling to the coating and pull it away from the pipe when the soil shrinks by drying; or irregular pressure in the trench may distort the bitumen and cause thin spots in the coating. In such soils a shielding material should be used to prevent damage to the coating by soil stress. Experience shows that many bituminous coatings that otherwise would have afforded adequate protection have been destroyed or rendered ineffective in this way. Thin, stiff, rolled steel sheet (26 gage) or copper foil may be used as a shield. Asphalt mastics consisting of 30% bitumen and 70% of a graded sand have been used with good results, especially for protection of pipe conveying hot oil through very corrosive soils. These mixtures are applied about $^3/_8$ in. thick, but are too expensive for ordinary use, costing about 60 cents per ft. on 8-in. pipe.

In soils where the electrical conductivity is high and fairly uniform, as in New Orleans, it has been found practicable to maintain the coated pipe lines at lower potential than the soil by imposing a current on the pipe to prevent the destruction of coating wherever it happens to be broken.

**PORTLAND CEMENT CONCRETE** has been used for over 40 years for protecting pipe in highly corrosive soil. It has a record as one of the most practical means of affording permanent protection. The minimum thickness usually is about 1 in., the mixture being applied in a wooden box surrounding the pipe. A portable steel form has been developed so that a concrete mixture consisting of 3 sand and 1 Portland cement can be poured around the pipe with a minimum thickness of $^5/_8$ in. Portions of the Hetch Hetchy steel conduits have been protected with such a mixture applied $^1/_2$ in. thick, wrapped with fabric. (*Construction Methods*, Dec. 1931, pp. 22–26.)

Portland cement coatings are applied in such thicknesses at about the same cost as fabric-wrapped bituminous coatings, and are highly durable in most soils, the cost of application being about 13 cents per lineal foot on 8-in. pipe. Concrete coatings offer some resistance to stray electric currents but should not be relied upon to protect pipe against electrolysis. Where pipe lines pass under electric railways, or in situations where complete electrical insulation is necessary, the line has been effectively protected by boxing and coating with hot asphalt with a minimum thickness of about 1 in. for a distance of 100 feet on each side of the track.

A comprehensive test of pipe coatings is now (1935) being conducted under the auspices of the U. S. Bureau of Standards with the co-operation of committees of the Am. Gas Assoc. and A.P.I. These tests are being made on short lengths of pipe, and also on operating oil lines. They should give useful information in a few years concerning the durability of all the material now available for such protection.

# CORROSION RESISTANT METALS*

## 1. STAINLESS STEEL

**STAINLESS STEEL.**—Alloys of iron, chromium and nickel are grouped under the general name of stainless steel. They are in three general groups. 1. Chromium-iron, with moderately high carbon. 2. Chromium-iron, with carbon under 0.12%. 3. Chromium-nickel-iron with low carbon. The various grades have been standardized by the producers of stainless steel under type numbers as shown in Table 1.

**Table 1.—Analyses of Standard Grades of Stainless Steel**

* Staff contribution.

These alloys are resistant to oxidation and generally to attack by acids, salts and organic substances, with the exception of carbolic, hydrochloric, hydrofluoric, phosphoric and dilute sulphuric acids, bleaching powder, the calcium, sodium and stannous hypochlorites, and the copper, ferric and mercuric chlorides. They also are subject to attack by wet or dry chlorine gas and molten zinc. The resistance to corrosion and attack of the various alloys by various reagents differ, and manufacturers should be consulted regarding the particular alloy for a given purpose.

A wide range of physical properties may be obtained with these alloys. The 18 Cr, 8 Ni group has a modulus of elasticity of (annealed) 28,600,000 which may be reduced to 22,000,000 by cold working. That of the 22 Cr, 11 Ni group is 29,000,000 annealed, and 22,000,000 cold worked. The modulus of shear of the two groups is respectively 11.9 and 11.2 million. Tensile properties at elevated temperatures are given in Table 2. Other physical properties are given in Table 3.

The effect of annealing on the physical properties of alloys containing nickel is given in Table 4. The effect of hardening and tempering at various temperatures of alloys containing no nickel, is given in Table 5. Creep stress is given in Table 6 and the fields of service or uses of the several alloys are given in Table 7.

The characteristics of the various groups vary widely in their reaction to heat treatment. In the first two groups, the steels with up to 18% Cr harden when cooled rapidly

* Cold-rolled, annealed. † Hot-rolled, annealed.

from above 1500° F. With Cr below 15%, they harden intensely when air-cooled from above 1500° F. Depending on the Cr-C combination, the Brinell hardness may be as high as 600. With Cr from 15 to 18%, the Brinell hardness, in the lower carbon ranges, may be as high as 300, but for the high-carbon steels, *i.e.*, steels containing 0.70 carbon, they may run as high as 600 Brinell. Steels with Cr above 18% harden to a much smaller extent, depending on the carbon content. Because of this air-hardening, these steels, when rapidly cooled from 1500° F. are not highly resistant to shock, and annealing or tempering usually is necessary to improve their shock resistance. Steels with Cr over 20% do not harden when rapidly cooled. Annealing has little effect on their properties. When subjected to long-time heating above 1750° F., they are brittle when cold. As this brittleness is due to the large grain formed, it cannot be corrected by heat treatment. When cooled slowly from above 1200° F. they are brittle when cold, but this brittleness may be removed by heating to above 1200° F. and cooling rapidly by water quenching. While steels of this composition are classified as brittle, and will break if subjected to violent

| Furnace parts | B, D | | |
| " " low temp. | E | | |

shock when cold, they still are sufficiently ductile to withstand normal handling operations.

Steels of the third group, when subjected to temperatures between 800° F. and 1500° F., are less resistant to corrosion. Under severe corrosion conditions they gradually will lose ductility and become brittle if the time of heating is sufficiently long. The rate at which this change takes place depends on the composition. When the time of heating is short, as in a welding operation, the selection of steels with a low carbon content will prevent a change sufficient to render the steels susceptible to attack. The same result may be obtained by increasing the chromium or nickel content. If, however, the steels are to be subjected to this temperature range for a long time, the addition of titanium or columbium in sufficient quantity will render them immune to intergranular corrosion. It has not been found possible to deposit titanium in weld metal. Consequently, if the titanium-bearing steels are welded, the weld metal itself will be subject to intergranular corrosion when the steels are heated in the temperature range 800–1500° F. and subjected to severe corrosive conditions. This change, which occurs in these steels after exposure to the temperature range 800–1500° F. for a long period of time, can be corrected by subsequent annealing at about 1900° F., followed by rapid cooling. If maximum ductility is required, an annealing temperature of 2100° F. is better, but large grain is apt to form unless the time of high temperature application is held at a minimum. See articles by C. A. Scharschu, *Metal Progress*, May, June and August, 1931.

**FABRICATION OF STAINLESS STEEL.**—The following notes on fabrication apply to all varieties of the stainless steels excepting as noted. Manufacturers should be consulted concerning special conditions.

**Welding.**—Stainless steels can be welded electrically with the metallic arc, the carbon arc, by the resistance method, the atomic hydrogen method, and can be seam-, butt-, spot- or line-welded. They also can be welded by the oxy-acetylene flame. Electric welding is preferred.

For oxy-acetylene welding, tips one or two sizes smaller than used for steel of the same gage are used. Uncoated rod of the same composition as the parts to be welded is necessary. The flame should be slightly reducing, cover the weld at all times, and be pointed in the direction of the weld. The weld should not be puddled. The parts should be preheated to 300–400° F.

Metallic arc direct-current welding requires that the work be negative and the welding rod positive. The welding rod should be low-carbon coated with a non-carbonaceous flux, and with Cr and Ni high enough to compensate for evaporative losses, so that deposited metal is of the same composition as the work. Gages heavier than No. 14 should be scarfed. A medium short arc should be used. If the weld is to be ground a light bead should be flowed on the side of the work to be ground and a heavy bead on the opposite side. The weld should be in the direction of current flow and should not be puddled.

The oxide should be removed from previously deposited metal before striking the arc.

Metallic arc alternating-current welding is used only on No. 16 gage work and lighter. The technique is the same as for direct-current welding.

Resistance welding requires heavier pressure but lower power input than is necessary with steel of the same gage. The metal must be clean and free from grease and have good contact.

After welding, the bead is removed by rough grinding with a rubber bond wheel. The temperature of the metal must not be raised above 400° F. After grinding the joint should be polished.

**Annealing.**—The procedure varies with the character of the metal. Heating should be done in a muffle or semi-muffle furnace. The Cr-Ni steels should be annealed at from 1850–2000° F. Sections $^1/_4$ to $^1/_2$ in. thick should be held at 1850° F. for 30 min., or at 1950° F. or over from 3 to 5 min., followed by rapid cooling in air. Sections $^1/_4$ in. thick or over may require an air blast or water quench. The work should be cooled below red heat in less than 3 min. The steels of Types (see Table 1) 403, 410, 416, should be heated slowly to 1450–1500° F. Steels of Type 430 should be heated slowly to 1550–1600° F. A slightly reducing atmosphere should be maintained in the furnace. The work should be cooled in the furnace at the rate of 50° F. per hr. If it is air-cooled, the maximum temperature should not exceed 1450° F.

**Pickling.**—For the Ni-Cr steels the following solutions are used. 1. 38° Baumé nitric acid, 25%; hydrofluoric acid, 2%. 2. Nitric acid, 20%; hydrochloric acid, 2%. 3. 20° Baumé muriatic acid, 25%. All by volume. 4. 60° Baumé sulphuric acid, 10%; rock salt, 10% (by weight). Solution No. 1 gives a white pickle. Solution No. 2 gives a high luster finish, but attacks the metal more than No. 1. Solution No. 4 gives the ordinary white finish. Solution should be heated to 140–180° F. Either or both bath and work should be agitated, and the loose oxide scrubbed off. After pickling wash the work in hot water.

The steels without Ni should be pickled in a solution of 10% muriatic acid by volume, heated to 140 to 160° F. Immersing in a 5 to 10% solution of nitric acid at 140–160° F. produces a white finish. The work should be washed in hot water after pickling.

**Shearing.**—About twice the energy necessary for mild steel is required. The knives must be sharp and closely adjusted, or the steel will be drawn over the bottom knife and work-hardened. The Cr-Ni steels must be cut all the way through, while the steels without Ni do not work-harden and will break after being cut through 50–75%.

**Blanking and Punching.**—For the Cr-Ni steels a neat clearance between punch and die is necessary or the metal will work-harden. About twice the power necessary for mild steel is required. For steels without Ni, the same practice as used for mild steel is recommended, but more energy is required.

**Forming and Drawing.**—The best drawing compound is white lead, thinned with linseed oil to about the consistency of 600W engine oil. Slow press speeds are necessary. For the Cr-Ni steels the clearance between punch and die should be greater than for mild steel, and a larger radius on the draw ring is advisable. Rough dies will cause trouble. The work should be annealed after drawing, being first cleaned thoroughly of oil and grease. For cleaning, sodium-metasilicate, at 160–200° F., or the electrolytic process, should be used.

The steels without Ni have about the same ductility as deep drawing steel. They require heavier backing and heavier die sections than steel, but the die clearances and speeds are the same as for steel. Steel of Type 446 is not suited to deep draws.

**Drilling.**—High-speed steel drills, ground slightly flatter than standard, should be used. A triangular-nose center punch should be used, the center punch mark being as shallow as possible to avoid work-hardening. Continuous pressure on the drill is necessary. The work should be backed up with a cast-iron backing plate, so that the drill will cut all the way through. Cutting speed should be about one-half of that for mild steel. The drill should be immersed in water after each hole. For deep holes, a compound of 1 lb. sulphur and 1 gal. of lard oil is advisable.

**Sawing.**—For the Cr-Ni steels, use a high-speed steel blade with wavy teeth. For light gages, use saws with 32 teeth per 1 in., with fewer teeth for heavier gages. The speeds recommended by saw makers should not be exceeded. For the steels without Ni, use the same methods as for 0.30–.40 carbon steel.

**Machining.**—For the Cr-Ni steels, speeds about one-half of those used for mild steel are best. Tool clearances should be about the same as for dead soft brass. The tool must cut at all times or the metal will work-harden. Taps should be ground as for dead soft brass, with slightly more taper and with but two or three full teeth. The best lubricant is water, 40 gal., lard oil, 10 gal., soda ash, 2.5 lb. For automatic machines, metal of 200–240 Brinell is best.

For the steels without Ni, the same practice as above is used with Types 430 and 446. For steels of Types 403, 410, 416, the same design of tool as used for 0.30–.40 carbon steel is used. These steels machine best at 220 Brinell. Slightly slower speeds are used than for steel.

**Spinning.**—For the Cr-Ni steels, speeds about one-half those used for spinning copper are advisable. Much greater power is required and the ordinary spinning lathes usually have insufficient belt pull. The best lubricant is white lead and linseed oil mixed to the consistency of a thick paste. The tool should be hardened steel, of the same design as for copper, except that it should be somewhat flatter. Frequent annealing of the work is necessary. For steels without Ni, the speed should be about two-thirds of those required for mild steel. The work requires annealing about one-third oftener than does steel.

**Riveting.**—Cold riveting is recommended for sizes less than $^3/_{16}$ in. The rivets should be set up in one blow. With the Cr-Ni steels, hot riveting should be done at temperatures of 1900–2100° F., and finished above 1600° F. Work exposed to corrosive conditions should be annealed after riveting. The steels without Ni should be hot riveted at the following temperatures: Types 403, 410, 416, below 1450° F.; type 430, below 1550° F.; Type 446, not over 1650° F.

**Brazing** is not recommended for any type of stainless steel.

**Soldering.**—Soft soldering should be avoided if possible. Silver soldering can be used for attaching steel to copper or steel to steel. For silver soldering the Cr-Ni steels to copper, use a flux of potassium acid fluoride and borax, and direct the flame on the copper. For soldering steel to steel, use the same flux and preheat slightly the areas adjacent to the joint. The flux should be removed immediately after soldering by a high-pressure steam jet. For steels without Ni, a solder should be used whose melting point is such that soldering can be done below 1500° F.

**Forging.**—The precautions usual in forging high-carbon steels should be observed. Forging of the Cr-Ni steels may be conducted at temperatures of 2150° down to 1700° F. These steels are stronger at high temperatures and harder to work. If a finished or semi-finished forging is to be pickled, it first should be annealed, otherwise surface cracks will develop.

The following temperatures are recommended for the steels without Ni: Types 403, 410, 416, 430, 2050–1600° F.; Type 446, 1950–1600° F. They should be slowly and uniformly heated to avoid rupture during heating. Forged bars at room temperature, which have not been annealed, should not be placed in furnaces whose temperatures exceeds 600° F. Special precautions should be taken to insure uniform cooling.

## 2. HIGH-SILICON ALLOYS

**CORROSIRON** is cast iron containing about 14.25% silicon, and other metalloids in small quantities. It melts at about 2400° F., and weighs about 0.263 lb. per cu. in. It is brittle with long flat crystals. A bar 1 × 2 in., 24 in. long, has a transverse strength of about 1200 lb., with the load applied at the center, the deflection being about 0.16 in. Shrinkage is about $^3/_{16}$ in. per ft. In designing, flat surfaces should be avoided, all corners rounded, and sections of metal kept as even as possible. The acid-resisting qualities of corrosiron are shown in Table 8. Corrosiron is used in the construction of pipes, valves, pipe fittings, acid pumps, pans, etc. It is made by the Pacific Foundry Co., San Francisco.

**Table 8.—Acid-resisting Properties of Corrosiron**

| Corrosive Agent | Concentration, percent | Depth of Corrosion, in. per yr. | Corrosive Agent | Concentration percent | Depth of Corrosion, in. per yr. |

**DURIRON** is a corrosion-resisting material made by the Duriron Co., Dayton, O., consisting of Si, 14.50%; Mn., 0.35%; C, 0.80 to 0.85%; Fe, balance. The following are given as its physical properties: Specific gravity, 7.0; weight per cu. in., 0.253 lb.; melting range, 2275 to 2375° F.; coefficient of expansion, 0.000 015 65 per deg. F., from room temperature to the melting point, and 0.000 004 per deg. F., from room temperature to 212° F.; electrical resistivity, microhms per cu cm. at 32° F., 63.3; thermal conductivity (silver = 1.000), 0.125; Shore scleroscope hardness, 49–51; contraction allowance in casting, 1/4 in. per ft. The makers give the tensile strength as 15,000–20,000 lb. per sq. in., and the compressive strength as 95,000 lb. per sq. in. Duriron will not soften or materially alter its shape at temperatures below 2000° F., nor does it oxidize at temperatures below 1500° F. It is highly resistant to erosion. Its corrosion resistance properties are given in Table 9, supplied by the makers.

**Table 9.—Corrosion-resisting Properties of Duriron**

## 3. NON-FERROUS ALLOYS

**COPPER-ALUMINUM-IRON BRONZE.**—Tests on copper-aluminum-iron bronze as an acid-resisting material, made at the Univ. of Wisconsin, were reported by O. L. Kowalke (*Chem. & Met. Engg.*, Jan. 7, 1920). Two bronzes of the following composition were tested:

| | Copper | Aluminum | Iron Alloy | Specific Gravity |
|---|---|---|---|---|
| Bronze A | 87.0 | 9.8 | 3.14 | 7.71 |
| Bronze B | 85.6 | 10.81 | 3.57 | 7.58 |

Bronze A is resistant particularly to sulphuric, lactic, phosphoric, tartaric and acetic acids and to caustic soda. Nitric acid attacks it readily, and hydrochloric acid and aqua ammonia both attack it too readily for commercial purposes. Bronze B is more resistant to sulphuric acid than Bronze A. It is less resistant to hydrochloric acid and more resistant to aqua ammonia than Bronze A, and also is attacked readily by nitric acid. The loss in weight, in grams per sq. in. at the end of 28 days of immersion was as follows:

| | BRONZE A | | | | BRONZE B | | |
|---|---|---|---|---|---|---|---|
| Temp. deg. F. | 72 | 72 | 72 | 194 | 85 | 85 | 194 |
| Strength of acid | 50% | 35% | 10% | 35% | 50% | 35% | 10% |
| Sulphuric acid | 0.0246 | 0.0177 | 0.0365 | 0.2520 | 0.0024 | 0.0044 | 0.0120 |
| Hydrochloric acid | ...... | 0.781* | 1.90 | ...... | ...... | ...... | ...... |
| Ammonia | 0.700 | 0.850 | 0.413* | ...... | 0.3810 | 0.3406 | 0.2237* |
| Caustic soda | 0.0007 | 0.0016 | 0.0055 | 0.0020† | ...... | 0.0022 | 0.0072 |
| Lactic acid | 0.0111 | 0.0132 | 0.0168 | 0.1550 | ...... | ...... | ...... |
| Phosphoric acid | 0.0114 | 0.0181 | 0.0281 | 0.0395 | ...... | ...... | ...... |
| Tartaric acid | 0.0028 | 0.0046 | 0.0077 | 0.0155 | ...... | ...... | ...... |
| Acetic acid | 0.0386 | 0.0312 | 0.0221 | 0.0713 | 0.0689 | 0.0442 | 0.0334 |

* At end of 21 days. † Gain due to formation of a film.

The corrosion of forged specimens of Bronze A in 35% sulphuric acid was only about one-half that of cast or rolled specimens.

**ILLIUM** is an alloy of nickel, chromium, and copper, developed by the Burgess-Parr Co., with the following average physical characteristics. Tensile strength, 60,000 lb. per sq. in.; elastic limit, 50,000 lb. per sq. in.; Brinell hardness, 170–200; melting point 2372° F.; specific gravity, 8.3; weight per cu. in. 0.3 lb.; specific heat 0.105 cal. per deg. C.; coefficient of expansion per deg. C. (20–300°), 0.0000135; electrical resistance 121.9 microhms per $cm.^3$; contraction in casting, $^5/_{16}$ in. per ft. Illium is readily machined, being slightly harder than cast steel, and may be welded to itself or other metals by acetylene or electric arc. It is resistant to the following: *Acids.*—Acetic, butyric, citric, formic, hydrocyanic, lactic, nitric, oleic, oxalic, phosphoric, picric, sulphuric. *Salts.*—Ammonium chlorate and sulphate, copper sulphate, ferric chloride, mercuric chloride, potassium alum, silver nitrate, sodium chloride, and hydroxide, hypochlorite and nitrite. *Organic Substances.*—Acid mine water, apple vinegar, carbolic acid, formaldehyde, fruit juices, malt vinegar. *Miscellaneous.*—Bleaching powder, bromide solution, carbonated water, hydrogen sulphide, sulphur dioxide. See *Product Engg.*, Nov. 1932.

Bureau of Standards (Circulars, Technologic Papers, Scientific Papers, Journal); *Equilibrium diagrams:* Landolt-Bornstein Tables (Physikalisch-Chemische Tabelen), vol. I, p. 527; Guertler's Handbüch der Metallographie; International Critical Tables, vol. II, p. 400.

**Structure Metallography.**—All metals and alloys are composed of an aggregate of grains, or crystals, the latter being in general *allotriomorphic*; *i.e.*, of internal crystalline nature but bounded by surfaces having no necessary relation to the crystalline structure. These grains vary greatly in size in different materials and under different treatments; grains have been observed as large as 1 in. and as small as 0.0001 in. in mean diameter. The grain structure of a metal, or alloy, may be revealed by polishing and etching with acid or other reagent, or in its fractured surface, and usually is observed under the microscope. It is now generally considered that these grains are bound or cemented together at the boundaries by extremely thin films of so-called amorphous metal; *i.e.*, of the same composition as the grains themselves but not crystallized or *anisotropic.*

The metal comprising the grain consists of atoms arranged upon a regular pattern known as *space lattice.* Most of the workable metals have *cubic* or *hexagonal* lattices; hard and brittle metallic crystals frequently have lattices of great complexity. Many unique properties of metals originate from this symmetrical arrangement of atoms in planes. Atomic spacings in metals, or *lattice constants*, range from 10 to 22 billionths of an inch. This *fine structure* of metals is revealed and studied only with x-rays or other short radiations.

**PHASE RULE.**—The metals or chemical metallic elements consist of grains of one kind only; namely, those of the metal. Alloys may consist of one kind, or of a mixture of several kinds, of grains of different chemical composition and crystalline structure. *The phase rule* is a physical-chemical law which governs absolutely the number of simultaneously existent different kinds of crystal in alloys (when in equilibrium) and its relation to the chemical composition and temperature of the alloy. This rule as applied to alloys is:

$$C - P + 1 = F,$$

where $C$ is the number of constituent metals, $P$ is the number of constituent *phases*, or kinds of grain or crystal (liquid phases also are recognized), and $F$ is the number of *degrees of freedom* in variation of composition or temperature.

**THE EQUILIBRIUM DIAGRAM** of an alloy series describes graphically the equilibrium condition of the alloy of any composition and at any temperature; it is a temperature-composition graph based on observed facts, which, however, are related according to the phase rule. Figs. 1 and 2 show two types of equilibrium diagrams commonly encountered in binary alloy series; *i.e.*, alloys composed of two metals only. From these diagrams the course of solidification from the liquid, or molten state, or of other crystallization may accurately be followed. Two metals may be completely soluble in each other, *i.e.*, in all proportions, either in the molten or liquid state or in the solid state, or they may have limited solubility. In the former case only one *liquid phase* or solid phase is formed, no matter what the proportions of the constituent metals; in the latter case an excess in relative amount of either metal over that which is soluble in the other will give rise to the formation of two phases or kinds of crystal which will coexist in equilibrium. The addition of one metal to another in the liquid state depresses the melting or solidification temperature, if it is soluble in the liquid state and not (appreciably) soluble in the solid state; if soluble in the liquid and solid state the temperature of solidification of the resulting alloy may either be depressed or raised.

On the equilibrium diagram the *liquidus* curve is the locus of temperatures at which solidification normally begins upon cooling the molten alloy. The *solidus* curve is the locus of temperatures at which melting normally begins upon heating the solid alloy. These curves are conjugate ones and pairs of points on the two curves connected by a horizontal line of equal temperature represent respectively the compositions of liquid phase and solid crystal in equilibrium. (See *l* and *s*, respectively, Fig. 1.) The composition of the crystal first formed upon solidification from a molten alloy is not, in general, the same as that of the liquid from which it crystallizes. It is due to this fact that *cored* or *dendritic* structures always are observed in cast alloys, not annealed or otherwise treated. Upon cooling and solidification the crystals first separating are richer in the constituent metal whose melting point is higher than that of the liquid. The process of setting or solidifying is too rapid to permit of equalization of composition through diffusion; consequently the last portion of the liquid to solidify is enriched in the constituent metal of lower melting point. A skeleton, or tree-like structure of the first crystals results, within the interstices, or arms, of which have solidified the last portions of the alloy which are much leaner in the metal of high melting point.

The mechanical mixture of two crystals forming simultaneously at the junction of two liquidus curves is called a *eutectic*, and the constant temperature at which it completely crystallizes is called the *eutectic temperature.*

Other relations than those discussed above are possible. *Allotropic transformations* at invariant temperatures may occur in either, or both, of the constituent metals, resulting in corresponding crystal and phase changes in the alloys. The temperature, or temperature range, at or within which phase changes resulting from allotropic transformations in metals or compounds, or intermediate crystal phases, occur on heating or cooling an alloy, is called *critical temperature* or *critical range*. These phase changes are *reversible* if they occur at the same temperature on heating as on cooling; a *temperature lag*, which in some cases may be as great as several hundred degrees Centigrade, occurs in the case of *irreversible* transformations. *Intermetallic compounds* may be found between metals and behave, and are represented in the equilibrium diagram, like metals.

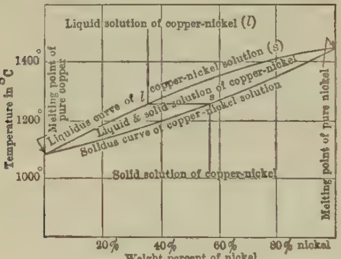

Fig. 1

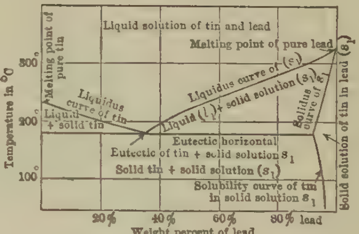

Fig. 2

**GRAIN SIZE AND GROWTH.**—Cast metals, as a rule, are coarser grained than metals that have been worked and annealed. The grain size of wrought metals is set by conditions of working and annealing. Cold-worked metal generates new grains when heated, beginning at a characteristic *recrystallization temperature*, above which the grain size developed increases with rise in annealing temperature. Heavy cold-working tends to lower the recrystallization temperature and to produce finer and more uniform recrystallized grains. A considerable increase in duration of annealing increases grain size less than a moderate rise in annealing temperature. Grain growth is not a reversible process; coarser grains can be developed readily by re-annealing at a higher temperature, but finer grains cannot be produced by re-annealing at lower temperatures, except through intervening cold work. An exception is metals having allotropic transformations, as steel.

Grain size in ingots and castings is determined by conditions during solidification, slow freezing promoting coarseness of grain. Thus, high casting temperature, heavy sections and sand molds tend to produce large grains, while chilling, thin sections and agitation promote fine grains. Centrifugally-cast shapes are fine grained. Heavy ingots are apt to have a coarse structure, which is broken up by working only with difficulty. Coarse, column-shaped grains result from large temperature gradients during freezing.

Some properties of metals are closely related to grain size. Those which are considerably affected are tensile and compressive strengths, ductility, impact toughness, hardness, magnetic hysteresis and permeability; on the other hand, elastic modulus, density, electrical properties, magnetic saturation, induction, thermal conductivity and expansivity are very slightly affected, if at all. Fineness and uniformity of grain are sought when high and uniform strength, toughness and ductility, or good deep drawing properties are desired; coarse grain is a desirable condition in some high-permeability magnetic alloys, and in metals from which strength at the highest temperatures is required.

Grain size customarily is expressed as *average grain diameter*, *i.e.*, $\sqrt{A/N}$, where $A$ = area of some plane section, and $N$ = the total number of grains visible upon it; it alternatively may be expressed as the number of grains per square inch, and usually is measured with a microscope. Grain sizes in metal range from 0.000 002 in. in hardened steel to 1 in. or more in some transformer steels or in castings; annealed non-ferrous metals with good mechanical properties usually range between 0.0005 in. and 0.005 in. average diameter. Sheets or strip for deep drawing often develop a pebbled or *orange peel surface* after drawing, if the grain size is over about 0.004 in. diameter. Standard grain size classifications for steel (A.S.T.M. Standard E 19) are:

| No. | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
|---|---|---|---|---|---|---|---|---|
| Grains per sq. in. at 100 × | Up to 1.5 | 1.5–3 | 3–6 | 6–12 | 12–24 | 24–48 | 48–96 | Over 96 |

**PHYSICAL PROPERTIES AND STRUCTURE, COMPOSITION AND TREATMENT.**—The mechanical and physical properties of metals and alloys primarily are determined by the chemical composition, the structure and the thermal and mechanical treatment to which they have been subjected, and may be controlled with some precision or varied through wide or narrow ranges by suitable variations in these factors.

The mechanical properties; *i.e.*, hardness, ductility, tensile and compressive properties of alloys depend quite markedly on their chemical composition, although no precise laws are known by which the relation of these qualities to the composition may be described. In general, the addition of one or more metals, in relatively small quantities, to another, causes an increase in hardness and tensile strength and a decrease in ductility. If the added metals go into solid solution in the original metal, the ductility may increase as well (the brasses and cupro-nickel). Ductility seems uniformly to be impaired by the addition of elements which result in the formation of two or more constituents in the alloy. For this reason, commercially useful alloys generally are composed predominantely of one metal, as the alloys in which both or all metals are present in large proportions are apt to be too brittle to be serviceable. The *hardening power* of different metals in conjunction with any other is, roughly, inversely proportional to the percentage of it which is necessary to exceed its solubility in the solid solution formed, or to form the first eutectic. The mechanical properties also are markedly affected by thermal and mechanical treatment.

**HARDENING OF METALS.**—A characteristic of metals is their hardening capacity, or ability to be changed in hardness by treatment to suit requirements. The term *hardness* describes a property defined as *resistance to permanent deformation*, and usually is measured with indentation instruments. It often is used in special senses, connoting difficult degrees of machinability, resistance to abrasion, or simply strength. Metals, including alloys, owe their hardness ultimately to forces between atoms composing the space lattice, and have exceedingly great potential strengths which are not obtained in practice due to the lack of complete continuity in structure and tendencies to rupture by degrees. Thus, wires and filaments generally have greater tensile strengths than metals in bulk. A result of the crystalline structure of metals is low shearing strength along lattice planes, and metals begin to distort by slippage without fracture within grains. Anything which obstructs slippage increases hardness and strength, and the various hardening treatments resolve into this ultimate principle. Cold-working causes slip and fragmentation which by mutual interference hinder further slip. Small hard particles, *e.g.*, of another crystal or foreign substance, scattered within the grain, act mechanically as keys to hinder slip. This action improves as the particles become finer; the most effective size or *critical dispersion* is about one ten-millionth inch. The *dispersion theory* of hardening considers the quench-hardening of steel, the spontaneous aging of duralumin and the temper hardening of certain non-ferrous alloys as examples of this, and heat treatment response as the dissolving or throwing out of solution of these keying particles by changes in temperature.

**EFFECT OF TEMPERATURE.**—Two effects of temperature on metals are distinguished: temporary, in which properties characteristic of the temperature are acquired; and permanent, in which changes occur which persist upon return of the metal to normal temperatures. The art of heat treatment is built upon the latter. At low, sub-atmospheric temperatures many steels and iron alloys become quite brittle, while certain nickel and copper alloys remain tough. At high temperatures, not only are metals subject to atmospheric attack, or *scaling*, but take on characteristics which are not readily disclosed in brief tests. *Flow* under sustained loading, which is absent in elastic materials at ordinary temperatures, becomes the dominant characteristic at temperatures beginning considerably below the softening range, and fracture may finally occur with stresses as little as $^1/_{10}$ the breaking stress found in ordinarily rapid tension tests. Within or below the softening range, flow diminishes with time, due to accumulation of work-hardening effects, and *creep stresses* are designated (European terminology differs) with reference to temperature and rates of stretching, *e.g.*, 1% elongation in 100,000 hours. For data on high and low temperature properties consult A.S.T.M. Symposium on Effects of Temperature on Metals, 1931.

**TREATMENT OF METALS.**—When a metal or alloy is deformed in the cold, as by rolling, hammering, swaging or drawing, its hardness and tensile strength increase and its ductility decreases. These changes are roughly proportional to the amount of deformation, usually expressed as percentage reduction in cross-sectional area, or reduction in thickness in the case of rolling. The hardness and tensile strength of ductile alloys thus may be increased two, and even three, times with, however, relatively much greater loss in ductility (to $^1/_{30}$ or $^1/_{50}$). Very heavy working develops fiber both as to included particles and grain structure, which results in difference in properties in different directions, *e.g.*, longitudinal *vs.* transverse. Once developed, this fiber structure may persist after annealing. Overworking results in edge cracking, internal bursts and other permanent impairments of quality. *Hot-working*, as forging, rolling, or piercing does not alter the mechanical properties of the material to the extent that *cold-working* does, as it is accompanied by simultaneous annealing and restoration of original properties. In general, a metal is cold-worked below the range of annealing temperatures, and hot-worked within and above it; for example, zinc may be hot-worked at temperatures which would result in cold-working of steel. *Extrusion* is a form of hot working in which the metal is heated to a plastic condition and squirted through a die under heavy pressure.

Upon *annealing*, cold-worked metals recrystallize and grain growth occurs, accompanied by restoration of the original mechanical properties. It is found that there exists for each metal or alloy, temperature ranges including usually about 200° C. (392° F.), above which annealing is completed rapidly, *i.e.*, the ductility is restored and the hardness is reduced to normal value. Within this range the annealing is completed slowly, and below it the metal cannot be altered so markedly by heating. This is called the *softening range* for the alloy in question; softening ranges for common materials are given in Table 1.

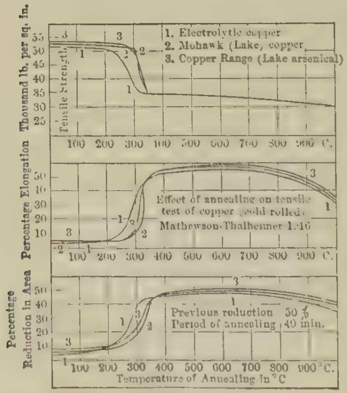

FIG. 3

Fig. 3 illustrates typically the effect of cold-working and annealing on the mechanical properties of metals; in this case, copper. In simple alloys, maximum softness results from annealing at the highest temperatures, while good combinations of mechanical properties, *i.e.*, fine grain, strength and ductility, result from annealing close to the softening range. The terms annealing and normalizing, while used more or less interchangeably to designate softening heat treatments for non-ferrous metals, have taken on specialized meanings in the case of steel. Annealing of steel consists in heating to a temperature above the critical range and cooling slowly, as in a large furnace; normalizing consists in cooling from that temperature freely in the open air. *Stress relief* annealing of cold-worked metal consists in heating at temperatures far below the softening range, *e.g.*, 200° C. (392° F.) for brass, 300–400° C. (572–752° F.) for Monel metal and steel; the metal remains hard but is improved in elastic properties and toughness, and internal stresses are dissipated.

Certain non-ferrous alloys with constituents of variable solid solubility are thermally hardenable. Such dispersion-hardening alloys are placed in a soft and workable condi-

Table 1.—Softening Ranges of Temperature of Various Metals and Alloys

| | Deg. C. | Deg. F. | | Deg. C. | Deg. F. |
|---|---|---|---|---|---|
| Zinc | 60–150 | 140–302 | Nickel-silver | 350–650 | 662–1202 |
| Aluminum | 200–400 | 392–752 | Iron and low carbon steel | 600–800 | 1112–1472 |
| Copper | 200–400 | 392–752 | Nickel | 600–800 | 1112–1472 |
| High Brass | 300–600 | 572–1112 | Monel metal | 600–800 | 1112–1472 |

tion by quenching from an appropriate temperature, and they then may be hardened by reheating for a considerable time, usually a number of hours, at some lower temperature. Table 2 gives heat treatment ranges for a few more important alloys.

**SURFACE TREATMENT** of metals to produce a hard or chemically resistant skin is accomplished by prolonged heating in contact with the impregnating substance or an unstable compound, and the surface alloy is formed by *diffusion* in the solid state; such are carburizing treatments of steel with carbonaceous solids or gases; nitriding with ammonia; zinc (sherardizing), aluminum (calorizing), chromium, as well as others.

**PHYSICAL PROPERTIES.**—The effect of composition and structure of alloys upon their other physical properties may be briefly considered. The *specific volume*, or reciprocal of the *density*, of alloys is approximately a linear function of the percentage composition, regardless of the type of alloy. This is true also of the *specific heat*. The *electrical conductivity* of binary alloys generally is linearly dependent on the volume percentage composition of the constituents when they are insoluble in the solid state, but is markedly less than this theoretical amount in the case of solid solutions. For this reason alloys for *electrical resistance purposes*, *i.e.*, copper-nickel, nickel-chromium, and iron-nickel, are chosen from among the latter type. The *temperature-coefficient* of electrical resistivity generally also is small in the case of alloys of the solid solution type having high values of the restivity. In general the *thermal conductivity* follows the electrical conductivity, being low in the case of solid-solution alloys.

There are given below some approximate relations between the various physical properties of metallic materials which may be useful for a rough orientation regarding the value of any particular one from a knowledge of others.

*Grüneisens relation:*

$$\frac{\alpha}{c_p} = n \quad \left\{ \begin{array}{l} \alpha = \text{coefficient of thermal expansion;} \\ c_p = \text{specific heat at constant pressure;} \\ n = \text{constant for each material independent of temperature.} \end{array} \right.$$

*Wiedemann-Franz law:*

$$\frac{k}{x} = nT \quad \left\{ \begin{array}{l} \left. \begin{array}{l} k = \text{thermal conductivity} \\ x = \text{electrical conductivity} \end{array} \right\} \text{in C.G.S. units;} \\ n = \text{constant varying from 5000 in the case of pure metals and} \\ \qquad \text{alloys without solid solutions to 7000 in the case of solid} \\ \qquad \text{solutions;} \\ T = \text{absolute temperature.} \end{array} \right.$$

*Richards relation:*

$$L = 2.1 \times m.p. \quad \left\{ \begin{array}{l} L = \text{latent heat per gram atom or molecule;} \\ m.p. = \text{melting point, absolute.} \end{array} \right.$$

The physical properties, as a rule, are not affected markedly by thermal and mechanical treatment. Electrical resistivity is increased and the temperature coefficient of resistance is diminished by cold-working; density, specific heat, elasticity, and thermal conductivity are only slightly altered by the most severe mechanical and thermal treatments. An exception is magnetic properties, which in ferro-magnetic materials often are highly sensitive to strain and heat treatment, and the development of exceedingly high magnetic quality requires painstaking attention to these details.

**TESTING OF METALS AND ALLOYS.**—For definitions of the physical and mechanical properties of metallic materials which usually are determined, see p. 7–03. For descriptions of the methods of test see p. 7–51. See also A.S.T.M. Standards, and A.S.M. Recommended Practice Committee (National Metals Handbook).

The engineer should take great pains to ascertain the exact relation of test results, or quoted information on metallic materials, to the problem of design or construction before him. In the case of rolled, forged, or drawn products not heat-treated, this may consist chiefly only in assuring himself of the accuracy of the data and in the consideration of the necessary factors of safety; the properties of the material going into his design or construc-

**Table 2.—Heat Treatment Ranges of Various Alloys**

| | Softening Quench | | Hardening Draw | |
|---|---|---|---|---|
| | Deg. C. | Deg. F. | Deg. C. | Deg. F. |
| Duralumin | 500–515 | 932–959 | Room temp. | Room temp. |
| "25 S" | 510–530 | 950–986 | 120–160 | 248–302 |
| Nickel bronze | 700–900 | 1292–1652 | 300–500 | 572–932 |
| Copper-beryllium | 750–850 | 1382–1562 | 250–350 | 482–662 |
| Copper-nickel-silicon | 750–900 | 1382–1652 | 350–550 | 662–1022 |

tion should be identical with those obtained in the ordinary tests. This is not true in the case of castings.

The mechanical properties of castings depend to a great extent on their mass and cross-section. It is the usual practice in obtaining tests on castings to pour either separately or in the same flask with the castings, from the same heat or melt, a test coupon of standard shape and section. The shape and section of this coupon varies with different materials and often unfortunately in different foundries for the same material. The properties determined from this coupon will be characteristic of the melt of metal from which it was poured, but characteristic only of the section and mass of the coupon, *not of the casting itself.* Generally speaking, hardness and tensile strength and elongation in the tensile test increase as mass and section of the casting decrease. For this variation allowance must be made, particularly in the design of castings of large mass and section.

**Non-destructive Inspections** often can detect internal flaws, as seams, cracks, holes or porous sections; for example, by disturbance in potential drop or of flux distribution when a standardized current or magnetic flux is passed through the object. x-ray radiographs reveal defects involving changes in density, as blowholes or cracks in welds, etc. Steel sections up to 4 in. thick are accessible to this method. A similar method utilizes the *gamma radiation* from radium or radium emanation.

Great caution should be used in the interpretation of corrosion tests, as slight differences in arrangement often develop great differences in result; tests carefully simulating all details of service frequently are necessary.

**FAILURES AND DEFECTS IN METALS AND ALLOYS.**—Commercial shapes, as rods, sheet, tubes, plate, etc., often are subjected to inspection for surface defects such as laps, seams, splits, cracks, blisters, or scale, which are due to a variety of causes extending throughout the manufacturing process and which vary with different materials. A commercially good shape is determined by practice and usage in each case, and general specifications for the presence, or absence, of such surface defects cannot be laid down.

**Pipe** in the ingot, or casting, often is the cause of defects in manufactured shapes. This is a shrinkage cavity formed by insufficient feeding of metal while pouring the casting, and usually is found in the upper central part of the casting. It often is accompanied by *segregation*, that is, the non-uniform distribution of impurities or alloying elements throughout the casting or shape made from it. In such cases there generally is a greater concentration of such impurities in the center of the ingot, casting, or resulting shape, than in the outer portions. It is due to selective freezing, whereas *liquation* is an actual separation taking place in the liquid or semi-liquid state and not necessarily directly related to the freezing. Lead may liquate in copper, carbon segregates in steel.

**Blow-holes or Gas-holes** in castings are formed by evolution of gas in the metal just prior to solidification in the mold.

**Contraction Cracks or Mold Pulls** in casting are the result of interference by parts of the mold, or core, with the natural contraction of the solid alloy, particularly through its temperature zone of weakness. Misplaced or shifted cores, washing of sand, and dirt in castings, blows, caused by wet sand or gas in metal, porosity, draws caused by shrinkage at changes in section, mis-runs due to lack of temperature, poor match of cope and drag, cold shuts also should be looked for in commercial castings.

**The Failure of Metals and Alloys** generally connotes mechanical failure by fracture, yielding, or cracking. *Yielding* of a metal or alloy indicates only that the applied stress was greater than its yield point or elastic limit. Examination usually is made of a fractured or cracked surface to determine the cause of failure. A detail fracture can be seen to originate at some point in the fractured section, generally a material defect of some sort. Mechanical failure from shear or torsional stress usually is observed readily from the character of the fractured surface. Fracture from direct static tension stress (that is, not changing or only slowly changing) should not occur in sound and ductile metals or alloys without appreciable elongation on both sides of the fracture. When a brittle or short fracture is observed in such materials, without appreciable elongation, the possibility should be considered of the failure having occurred by reason of the application of alternating or repeated stress, or as the result of a sharp blow or impact, and particularly if sharp offsets, shoulders, or grooves in the failed article tend to localize the stress and produce a notch effect. All metals if subjected to vibratory, repeated or reversed stresses ultimately will fail (after perhaps millions of such cycles) at intensities of stress much below that required to break in tension under steady loading. Such *fatigue failures* sometimes occur in shafts and other machine parts subject to rapidly changing loads. Under cyclic stressing, many metals show true *endurance limits*, *i.e.*, limiting stresses below which they will escape breakage indefinitely. The endurance limits of common metals and alloys range from 35 to 55% of their tensile strength. Some forms of corrosion accelerate fatigue failure. The oft-quoted explanation of mysterious failures of metallic materials—

that of their "crystallization" is utterly fallacious. The usual materials, iron, steel, brass, bronze, copper, etc., always are crystalline. When fractured in impact or under the action of repeated stress they often display a crystalline fractured surface, solely by reason of the fact that the path of break in such cases relates itself more definitely to the crystalline structure of the material.

**Season or Corrosion-cracking**, of certain metals and alloys often occurs without external applied stress, but as the result of internal stress in the material, combined with surface corrosion. Stress-relief annealing is the preventive measure. Factors controlling the corrosion of metals are too complicated for discussion here. Consult U. R. Evans, The Corrosion of Metals, Edward Arnold & Co.; see also pp. 3–03 to 3–19.

**ENGINEERING ALLOYS.**—The alloys of engineering importance are few compared with the almost limitless number of possible mixtures, and the tendency is toward greater standardization. A number of the engineering metals now are defined by specifications. Besides these, there are upwards of 1000 proprietary alloys, generally bearing names which do not suggest their composition, but similar to standard commerical alloys in properties. In addition, there are many obsolete alloys which have been described and have established a foothold in handbooks, but which no longer have distinctive qualities. The number is too great to list here. *Metal Industry*, London, publishes a handbook of Metals and Alloys which lists many of these by name. Prof. W. Campbell has published, through A.S.T.M. (1930) A List of Alloys. A list of corrosion-resisting alloys is given in *Chem. and Met. Engg.*, Sept., 1932 (p. 497). See also pp. 4–19 to 4–34.

**AMERICAN NON-FERROUS METAL SPECIFICATIONS.**—The principal standardizing agencies in the U. S. for metals are the American Society for Testing Materials, Philadelphia; the Society of Automotive Engineers, New York; the Federal Specifications Board, Bureau of Standards, Washington. D. C. The American Engineering Standards Committee publishes standard specifications for non-ferrous metals which are identical to those published by A.S.T.M. In addition, many manufacturing plants and railroads issue their own purchase specifications, copies of which often may be obtained on request. Many other standard specifications, dealing with metal manufactures and finished products, are indexed in the *National Directory of Commodity Specifications* (Miscellaneous Publication No. 130), obtainable from the Superintendent of Documents, Washington, D. C.

# COPPER

By W. H. Bassett

**PHYSICAL PROPERTIES OF COPPER** are as follows:

### General Properties

| | | | |
|---|---|---|---|
| Density | 0.322 lb. per cu. in. | Specific heat at 77° F. | 0.0917 |

**COMPOSITION OF COMMERCIAL COPPER.**—Specifications for copper, generally accepted by industry, are the A.S.T.M. standard specifications. These cover lake copper, electrolytic copper, and fire-refined copper. Lake copper, which must originate on the upper peninsula of Michigan, may be low-resistance or high-resistance lake copper.

**Low-resistance Lake Copper** is used for electrical purposes, and may be electrolytically or fire refined. It is required to have a content of (copper + silver) of not less than 99.900%. Maximum permissible resistivities in international ohms (meter, gram) are as follows: Copper wire bars, 0.15436; ingots and ingot bars, 0.15694.

**High-resistance Lake Copper** is lake copper of resistivity exceeding 0.15694 international ohm (meter, gram) at 20° C. Its (copper + silver + arsenic) content is not less than 99.900%.

**Electrolytic Copper** specifications for purity and resistivity are the same as those of low-resistance lake copper.

**Fire-refined Copper,** other than lake, is used for rolling into sheets and shapes. It is not acceptable for electrical uses or for wrought alloys. A.S.T.M. Specifications call for the following analysis: Cu + Ag, 99.700%; As, max., 0.1000%; Sb, max., 0.0120%; Bi, max., 0.0020%; Fe, max., 0.0100%; Pb, max., 0.0100%; Ni, max., 0.1000%; O, max., 0.0750%; Se, max., 0.0400%; Te, max., 0.0140%; Sn, max., 0.0500%.

**HARDENED COPPER.**—There are only two methods for hardening copper; namely by cold working it or by alloying with it small amounts of other elements such as silicon, tin, zinc, aluminum, etc. Both of these methods are in commercial use. When copper is hardened with tin, silicon, or aluminum it generally is called bronze; when hardened with zinc, brass.

**CORROSION.**—Copper is resistant to the action of sea-water, and to atmospheric corrosion. It is not resistant to the common acids, and is unsatisfactory in service with ammonia and with most compounds of sulphur. Manufacturers should be consulted in regard to its use under corrosive conditions.

**OXYGEN-FREE HIGH-CONDUCTIVITY COPPER** is a highly ductile material, made under conditions that prevent the entrance of oxygen and formation of copper oxide. It is utilized in deep drawing, spinning, and edge bending operations, and in welding, brazing, and other hot-working operations where embrittlement must be avoided. It has the same conductivity and tensile properties as tough pitch electrolytic copper.

**FABRICATION.**—Copper may be hot or cold forged, hot or cold rolled, hot extruded, hot pierced, and drawn, stamped, or spun cold. It can be silver-soldered, brazed, and welded. For welding by the oxy-actylene torch or electric arc, the oxidized copper will give more satisfactory welds than electrolytic or lake copper. Copper cannot be cut by the oxygen jet because of its high heat conductivity. Copper is annealed from 480 to 1400° F., depending on the properties desired, and in a slightly oxidizing atmosphere. Ordinary commercial annealing is done in the neighborhood of 1100° F. A reducing atmosphere will make the copper brittle and unfit for use. Copper may be electro-deposited from the alkaline cyanide solution, or from the acid sulphate solution.

**COMMERCIAL FORMS OF COPPER.**—Copper is produced in practically all commercial forms, *viz.*, wire, sheets, strips, bars, plates, seamless tubes and castings, and in most fabricated forms as screen, wire cloth, bolts, nuts, etc. For dimensions, see pp. 6–08 to 6–12 and 6–19 to 6–22. The following is a list of the specifications of copper for various purposes given in the 1936 A.S.T.M. standards:

Designation B4–27, Lake Copper Wire Bars, Cakes, Slabs, Billets, Ingots, and Ingot Bars; Designation B5–27, Electrolytic Copper Wire Bars, Cakes, Slabs, Billets, Ingots, and Ingot Bars; Designation B72–33, Fire-refined Copper, other than Lake; Designation B1–27, Hard-drawn Copper Wire; Designation B2–27, Medium Hard-drawn Copper Wire; Designation B3–27, Soft or Annealed Copper Wire; Designation B33–21, Tinned, Soft or Annealed Copper Wire for Rubber Insulation; Designation B8–36, Bare Stranded Copper Cable, Hard, Medium-hard, or Soft; Designation B11–33, Copper Plates for Locomotive Fireboxes; Designation B12–33, Copper Bars for Locomotive Staybolts; Designation B13–33, Seamless Copper Boiler Tubes; Designation B42–33, Copper Pipe, Standard Sizes; Designation B48–27, Soft Rectangular Copper Wire; Designation B49–26, Hot-rolled Copper Rods for Wire Drawing; Designation B68–33, Seamless Copper Tubing, Bright Annealed; Designation B75-30, Seamless Copper Tubes; Designation B88–33, Copper Water Tube.

# ZINC AND ITS ALLOYS

By W. M. Peirce

**References.**—U. S. Bureau of Standards Circular No. 395, Zinc and Its Alloys (1931), which includes a complete bibliography. Valuable bulletins on various subjects relating to zinc and its uses may be obtained from the principal producers of zinc and from the American Zinc Institute.

## 1. PROPERTIES OF ZINC

**CHEMICAL CHARACTERISTICS.**—Zinc is a chemically active metal. Its chemical properties are the reason for its use in primary cells, for cyaniding and in the production of nascent hydrogen. It forms both basic and acid radicals, and is soluble both in acids and strong alkalies.

**Atmospheric Corrosion.**—In pure distilled water zinc forms a loosely adherent film of hydroxide which affords little protection. This film, dried in the presence of oxygen and the traces of carbon dioxide always present in the atmosphere, forms a protective layer or film believed to be a zinc oxide-hydroxide-carbonate mixture. This is quite insoluble in rainwater, affords effective protection against further attack, and makes zinc a satisfactory roofing and flashing material. The presence of sulphur gases in industrial atmospheres increases the solubility of this film, accounting for the higher rate of weathering in industrial as compared to rural atmospheres.

**Effect of Organic Acids.**—Certain organic acids dissolve the atmospheric corrosion film on zinc. Acids formed by decomposition of red cedar and white cedar at ordinary temperatures, and of other woods at higher temperatures (as in steam) have this effect. Hence zinc cannot be safely used in contact with some moist woods or drainage from them.

**Resistance to Organic Substances.**—Zinc is inert to such common organic substances as gasoline, kerosene, oil, and grease free from water. Soap and soap paste do not attack it, though in dilute soap solutions there is a tendency to form zinc soaps. Zinc is entirely inert toward anhydrous alcohol, but is oxidized by mixtures of alcohol and water. Sugar solutions made up with hard water do not attack zinc when totally immersed at room temperature, but distilled-water solutions at any temperature or hard-water solutions at elevated temperatures attack it.

**Effect of Carbon Dioxide and Steam.**—Very high carbon dioxide concentrations appear to aid the solution of the corrosion film. Increased temperature sometimes may have the same effect. Live steam destroys the protective film and also attacks the metallic zinc at an increased rate. Hence unalloyed zinc is unsuitable for use when exposed to live steam.

**Effect of Oxygen Concentration.**—Severe corrosion of zinc occasionally occurs in the presence of a water film without free access of oxygen to all portions of it. An example is a zinc roof, laid over an absorbent sheathing and building paper, on a building having high humidity inside. If the roof is unprotected from condensation on the under side, rapid corrosion of the zinc may occur. The preventive is building paper, saturated and coated on both sides with asphalt, under the metal roofing.

**Toxicity.**—Excepting the salts of strong acids, which are corrosive, or zinc compounds containing other poisonous elements or radicals, the compounds of zinc are not strongly toxic. Zinc is a normal constituent in many foods and considerable excesses of zinc taken into the body are readily eliminated without ill effects. Excess zinc content in foods or beverages may cause unpleasant but not serious symptoms. Drinking water should not contain more than 40 mg. per liter.

**PHYSICAL PROPERTIES.**—The more important physical constants of zinc are given in Table 1.

**METALLOGRAPHY.**—The common impurities in zinc are lead, cadmium, and iron. Their importance varies individually with the use to which the metal is put. These metals, as well as copper, magnesium, and aluminum, which are the more common elements used in zinc alloys, are discussed below.

**Lead,** which does not enter into solid solution, has no great effect in unalloyed zinc. Its effect on the properties of certain zinc alloys, however, is enormous.

**Cadmium,** in the amounts present in commercial zinc, is completely in solid solution, and exerts an important hardening effect. It also raises the recrystallization temperature,

**Table 1.—Physical Properties of Zinc**

(Compiled from various sources)

| | |
|---|---|
| Atomic weight | 65.38 |
| Density (rolled), (see Note 1) | 445.8 lb. per cu. ft. |
| Melting point | 787° F. |
| Boiling point | 1661 ± 4° F. |
| Mean specific heat (68°–212° F.) | 0.0931 |
| Latent heat of fusion | 47.88 B.t.u. per lb. |
| Latent heat of vaporization | 768.2 B.t.u. per lb. |
| Coefficient of linear expansion | |
| Cast | $21.9 \times 10^{-6}$ Per deg. F. |
| Rolled, with grain | $17.8 \times 10^{-6}$ |
| Rolled, across grain | $12.8 \times 10^{-6}$ |
| Thermal conductivity | 784 B.t.u. per sq. ft. per hr. per 1 in. thickness per deg. F. |
| Electrical resistivity (see Note 2) | 2.33 microhm-in. |
| Temperature coefficient of resistance (0°–100° C.) | 0.00233 per deg. F. |
| Resonance | See Note 3 |

NOTES. 1. Solid zinc (rolled) is about 3% heavier than liquid zinc at the melting point.

2. Based on soft rolled zinc strip 99.99% pure. Resistivity of strip zinc may vary 3%, depending on rolling treatment, and in commercial grades about the same amount, depending on purity.

3. Rolled zinc has extremely low resonance, which permits its use in various sound apparatus.

and whereas pure zinc recrystallizes at so little above room temperature that it cannot be appreciably work hardened, zinc containing cadmium can be given a considerable degree of work hardening by cold rolling.

**Iron** has a limited solid solubility of the order of 0.001 to 0.003%. Attention must be given to the iron content of zinc for rolling.

**Copper** is the alloying element most frequently added to zinc. It enters into solid solution in zinc to about the same extent (approximately 1%), and with about the same effect, as cadmium, except that the copper-zinc alloys are more ductile and easier to roll. See pp. 4–18 to 4–33.

**Magnesium** has a solid solubility of 0.01 or 0.02% in zinc, but even these amounts exert a remarkable influence on its properties. When magnesium is added in the presence of copper, its effect is even more striking. Some of the most important zinc alloys contain both copper and magnesium.

**Aluminum** is limited entirely to zinc casting alloys, as usually zinc alloys containing aluminum are unstable when rolled. In the cast form, however, several percent of aluminum can be used to improve greatly the physical properties, particularly the tensile and impact strength of zinc. The alloys, if properly formulated, are stable.

## 2. SLAB ZINC

**COMPOSITION OF SLAB ZINC.**—A.S.T.M. Standard Specifications B6–33 for slab zinc (Spelter) gives the values of Table 2 for the various grades of slab zinc.

### Uses of Slab Zinc

**GALVANIZING** is the process of coating iron or steel with zinc as a protection against corrosion. The product is known as galvanized iron or steel. Zinc coatings are desirable not only because the zinc corrodes more slowly than iron but also because at cut edges or similar discontinuities in the coating, the zinc, being anodic to the iron, affords galvanic protection and the iron is not dissolved until the zinc has been completely removed by corrosion.

The protection afforded depends largely on the thickness of the coating. For protection indoors, a few tenths of an ounce is sufficient. For outdoor exposure a coating of at least $^3/_4$ oz. per sq. ft. of surface, and preferably 1 oz. or more is necessary.

The less pure grades of zinc commonly are used for galvanizing, but the coating so produced will not withstand much deformation without cracking and flaking. High-grade zinc nearly free from cadmium is used for galvanizing bridge wire, telegraph wire and other products that are subject to deformation such as twisting, etc., and for sheets that are to be fabricated after galvanizing.

The life of zinc coatings, regardless of the method of application, has been shown to be directly proportional to the thickness or weight of the coating. The proportion of pure zinc to iron-zinc alloys in the coating does not have any significant effect.

**Specifications and Tests for Galvanized Coatings.**—Galvanized coatings usually are specified as a given weight of zinc per unit area, *i.e.*, ounces of zinc per square foot of surface. For details of methods of determining the weight of the coating see Standard Methods of Determining Weight of Coating on Zinc Coated Articles, A.S.T.M. Specification A–90–33.

Specifications for most commercial products covering weight of coating and bend tests when required are available in A.S.T.M. Standards, 1936, Part I, Metals, and A.S.T.M. Tentative Standards, 1936.

On sheets, coating weights are given as weight per square foot of sheet, *i.e.*, 2 sq. ft. of coated surface. Ordinary coatings on sheets range from 0.75 to 2.75 oz. per sq. ft. of sheet coated on both sides. The weight of zinc per single covered surface would be one-half this amount. Zinc coatings on pipe, structural shapes, hardware, etc., generally

**Table 2.—Standard Specifications of Slab Zinc**

| | Grade | Maximum Allowable Percentages of | | | Lead + Cadmium +Iron not to Exceed |
|---|---|---|---|---|---|
| | | Lead | Cadmium | Iron | |
| 1a | Special high grade *† | 0.010 | 0.005 | 0.005 | 0.010 |
| 1 | High grade* | .07 | .07 | .03 | .10 |
| 2 | Intermediate* | .20 | .50 | .03 | .50 |
| 3 | Brass special* | .60 | .50 | .03 | 1.00 |
| 4 | Selected* | .80 | .75 | .04 | 1.25 |
| 5 | Prime western | 1.60 | ........ | .08 | .......... |

* All grades except prime western must be free from aluminum. †Tentative standard.

range between 1.15 and 3.5 oz. per sq. ft. of covered surface. The weight of coating on wire varies with the size of wire and process of coating, and, except in fine sizes, will range from 0.15 to 1.25 oz. per sq. ft. of covered surface.

**METHODS OF APPLICATION.**—Galvanized coatings are applied: (*a*) by dipping the article in molten zinc, (*b*) by electroplating, (*c*) by heating in contact with zinc dust.

**Hot Dip Galvanizing.**—The iron or steel is cleaned by pickling, usually in hot sulphuric acid. A rinse and a dip in cold hydrochloric acid usually follow, but better practice involves removal of iron salts from the pickled material by vigorous rinsing and scrubbing if necessary, followed by dipping in slightly acidulated 25% zinc chloride. After partial drying, the material enters the bath of molten zinc, sometimes through a flux of zinc ammonium chloride. A solid layer of iron-zinc alloy forms on the iron surface in a few seconds. The longer the immersion, the thicker the alloy layer. The material is withdrawn from the zinc bath through rolls kept clean by zinc ammonium chloride flux in the case of sheet, or through a charcoal sand or asbestos wipe in the case of wire. Speed of withdrawal and character of wipe influence the thickness of the layer of molten zinc adhering to the work. Tin may be added to the zinc bath to produce a sheet with bright spangle. Aluminum may be added in hand dip galvanizing of pipe, shapes, and hardware to produce a smooth coating. The vapor of burning sulphur or ammonium chloride dust sometimes is blown over the surface of sheets to improve brightness.

**Electrogalvanizing.**—Zinc coatings may be applied to wire, conduit, and hardware by electroplating. The only distinguishing feature of this process, as compared to other electroplating processes, lies in the attention given to methods of rapidly depositing heavy coatings (*e.g.*, the patented Tainton Process), since the serviceability of the coatings depends on their thickness and the thickness ordinarily desirable is greater than in purely decorative plating. This method of zinc coating avoids changes in the base steel due to heat and does not produce excessive deposits in recesses, such as the base of threads, which would affect dimensional tolerances.

**SHERARDIZING.**—Zinc and iron alloy readily, and coatings therefore can be produced by heating iron or steel with zinc dust in a closed vessel for several hours. The vapor pressure of the zinc is sufficient at the temperatures used, 600–700° F., to cause a reaction of zinc vapor with the iron. It has been demonstrated that alloying will occur by diffusion at only slightly elevated temperatures. The resulting coating, which is quite uniform, is almost entirely iron-zinc alloy, richer in iron near the base metal, with some mechanically held zinc dust in the outer layers. See also p. 3–14.

Sherardizing may result in some heat treatment of the base metal. Sherardized coatings, like coatings of iron-zinc alloy produced by other methods, afford an excellent base for paints or enamels. The coating itself is a matte gray and can be polished. Like other coatings consisting almost entirely of iron-zinc alloys, sherardized coatings dust, rather than flake, on bending. Also in common with such coatings the protection afforded by a given thickness is, under the average normal service conditions, equal to the protection afforded by an equal thickness of pure zinc. The zinc dust used may be the by-product blue powder from spelter furnaces, or it may be expressly manufactured for the purpose, attention being given to a suitable particle size and metallic zinc content.

**BRASS.**—See p. 4–18. The second largest use of zinc is in the manufacture of brass. Brass alloys are discussed in detail on pp. 4–18 to 4–33. Since lead is objectionable in brass used for drawing, grades of zinc low in lead are largely used in brass manufacture.

**DIE-CASTING.**—Suitable alloys for die-casting require zinc of exceptional purity, and the Special High-grade specification listed above is drawn primarily to define a suitable grade for use in zinc die-casting alloys. Freedom from lead, tin, and cadmium is the primary requirement. By alloying with about 4% aluminum, a few hundredths of 1% magnesium, and in some cases 1 to 3% copper, alloys amenable to die casting, and having in the die-cast condition radically improved properties as compared with unalloyed zinc, are obtained. See also p. 4–60.

**SLUSH CASTING.**—High grade slab zinc is used in slush castings, largely used for lighting fixtures and other ornamental parts. High grade unalloyed zinc is used, and also alloyed zinc containing small percentages of aluminum, and sometimes of copper.

## 3. ROLLED ZINC

**CLASSIFICATION OF ROLLED ZINC.**—Rolled or wrought zinc is classified as follows (see A.S.T.M. Standard Specifications for Rolled Zinc, B 69–29):

Type A. Ribbon zinc and sheets or strips cut from ribbon zinc which has been rolled from a single bar in one continuous direction.

Type B. Sheet zinc or strips cut from sheet zinc that has been rolled by the pack rolling method.

Type C. Boiler and hull plates, which may be rolled either from a single bar or by the pack rolling method.

**Strip Zinc** may be obtained in coils or flat lengths in thicknesses from 0.006 to 0.050 in. and in flat lengths up to 0.10 in. Depending on the gage, maximum width varies from 12 to 20 in., but widths less than 12 in. are obtainable in any gage. Lengths of coils may vary from 100 to 250 ft. in heavy and medium gages, and up to 1600 ft. in the lightest gage. Dimensions of sheets range as follows: Thickness, from 0.006 to 0.10 in.; width, 18 to 60 in.; length, 72 to 144 in.

**Boiler Plates.**—Plates of rolled zinc, usually about 1/2 in. thick, termed boiler plates or hull plates, are attached to the inside of boilers or to steel hulls to give galvanic protection against corrosion. The steel is protected at the expense of the zinc, which dissolves.

**ZINC GAGE.**—Table 3 compares the standard zinc gage and the American or Brown & Sharpe gage and the U. S. Standard gage and gives the tolerances permitted. The use of this special zinc gage is discouraged and, to avoid errors, the actual thickness, expressed in thousands of an inch, is preferable.

**Table 3.—Comparison of Zinc Gage and Other Gages**

| Brown & Sharpe Gage, Approximate Thickness | | U. S. Standard Gage, Approximate Thickness | | Rolled Zinc Gage | | | Permissible Variation in Thickness of Rolled Zinc* | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|

* Permissible variations in thickness of Type C rolled zinc are the same as those for either Type A or Type B, depending on whether the material is cut from a ribbon or a sheet.

**TESTING METHODS.**—The properties of zinc depend largely on the rate of loading. It is important that tests be made at rates of deformation that approach those which occur in service. Thus a cupping test, to indicate the suitability of strip for drawing, must be made at the speed of a draw press operation. At the other extreme, corrugated roofing sheets, which must continuously support static loads, must be tested under static load for long periods.

A.S.T.M. Specification B 69–29 calls for temper and dynamic ductility (cupping) tests. These are considered the only ones sufficiently reproducible and valuable for test purposes.

**Temper** is measured by a testing machine which wraps a specimen tightly around a mandrel to which one end of the specimen is clamped. The degree to which the free end springs away from the mandrel is measured on an arbitrary scale, ranging from 0, representing no spring whatever, to 100, representing material that returns to its original straight condition.

The three types of rolled zinc are classified according to temper as follows: Type A: dead soft, soft, half hard, and hard; Type B: commercial; Type C: no classification. It should be noted that the terms soft, dead soft, etc., serve to designate certain specific ranges of properties regardless of the combination of composition and rolling treatment by which the properties are obtained. Table 4 gives the temper requirements of Type A and Type B rolled zinc.

**Dynamic Ductility** is determined by forming a series of cups by forcing a spherical-ended plunger into a test strip, the plunger being adjustably mounted in a drawing press to permit varying the depth of the cup. The maximum depth of the cup, in inches, which can be formed before visible "necking down" occurs is the dynamic ductility. See Table 4 for dynamic ductility requirements of the various types of rolled zinc.

**Tensile Strength,** as ordinarily measured, is of secondary importance in the application of rolled zinc. Other properties, as ductility and temper, must be controlled, which control fixes the tensile strength. Tensile strengths are not used generally in product control and rarely are specified. Percentage of elongation in the tensile test is of little significance, as the rate of loading, 0.25 in. per min., is far below the rate of deformation in commercial operations and is no index to the ductility in such work.

However, where tensile tests are required the A.S.T.M. standard tensile specimen for

* These properties are the minimum requirements for acceptable shipment when no special requirements have been specified.

thin sheet metal is entirely suitable for zinc. A pulling speed as near to 0.25 in. per min. as can be obtained on the testing machine should be used. Under these conditions, rolled zinc will have a "with-grain"* tensile strength varying from 18,000 lb. per sq. in. for soft temper high-grade zinc to 35,000 lb. per sq. in. for hard-temper prime western zinc. The elongation will vary from 5% for the hardest to 65% for the softest metal. The "across-grain" strength in every case will be a few thousand pounds higher and the elongation somewhat lower.

**Static Tensile Tests.**—Of much greater importance than the ordinary tensile test, from a practical standpoint, is the static tensile or creep test which determines the resistance of various grades of zinc to elongation or flow at different temperatures under static tensile load. This information has been correlated with actual loading tests on corrugated zinc roofing sheets. See Tables 5 to 7.

**Modulus of Elasticity** of zinc lies between 10,000,000 and 20,000,000, depending on the rolling treatment. Approximately 12,000,000 is a representative value for soft-rolled high-grade zinc.

**Shearing Strength** of high-grade zinc plates ranges from 17,000 to 19,000 lb. per sq. in.

**FABRICATION.**—The ductility of zinc falls off rapidly at temperatures below 70° F. All drawing and bending operations, therefore, should be performed at temperatures above 70°. Frequently an operation which is just too severe to be successful at temperatures near the lower limit may be successfully accomplished by warming the zinc and tools, for example to 100° F. In any type of extrusion, it is necessary to use an elevated temperature in order to operate with reasonable pressures. For certain ornamental sheet metal work heavy gage zinc is hand formed at temperatures as high as 480° F.

**Lubrication.**—In all operations where a lubricant is required, excepting those operations involving temperatures well above room temperature, soapy water is the cheapest lubricant, and is quite satisfactory. A neutral soap should be used to avoid staining. If finish is important, it may be necessary to avoid spotting by washing the work and then drying it in sawdust.

* The grain in rolled zinc is considered as running parallel with the direction of rolling.

† Trade Mark, Reg. U. S. Patent Office. A zinc-copper-magnesium alloy patented and sold by The New Jersey Zinc Co.

**Bending** usually is performed either on an ordinary brake or in forming rolls. When using a brake, the edges of the bending and clamping jaws should be rounded to the extent of at least removing the knife edge. If possible, bends in rolled zinc should be at right angles to the grain or rolling direction. It then is easy to obtain proper bending properties without the sacrifice of hardness and stiffness.

A *with-grain bend* is a bend, the edge of which is parallel to the grain. A with-grain temper test is one in which the grain is parallel to the length of the specimen. The bending then occurs across the short dimension.

Bends frequently must be made with the grain because of width limitations in strip zinc, or to take advantage of automatic machinery using coils of ribbon zinc. Zinc manufacturers should be consulted in regard to the best combination of high cold-bend value and high temper for the particular conditions involved. If no drawing operation is contemplated, the omission of dynamic ductility from the zinc specifications may be of advantage.

Temperature is most important in bending zinc, as in other forming operations. A slight warming of the metal sometimes makes possible an otherwise impossible bending operation.

**Drawing.**—Operations in which cups are formed from flat blanks, without any general reduction in gage, are termed drawing. Shop methods in drawing zinc vary considerably from one plant to another, but in general, brass practice is followed, with departures in detail depending on the particular operation. It is unnecessary to anneal pure zinc between operations, and the work-hardening alloys require fewer annealings than brass. Reductions in diameter from blank to the first cup should not exceed 45%. A somewhat lower reduction usually is preferable. It is possible to reduce the wall thickness 25 to 33% in redrawing operations in which the cup diameter is reduced 20%.

**Extrusion.**—Zinc is successfully extruded into any of the forms commonly produced by this process. Tubing and rod have been produced, but in the U. S. development has been limited principally to the production of cups, buttons, nails, etc. Blanks for the extrusion of small articles usually are punched from rolled metal, although cast billets have been used for rods. Because of the directional properties of rolled zinc, some trouble due to non-uniform flow is encountered in some classes of work. A specially-rolled zinc can be supplied to minimize this difficulty.

**Welding** of zinc requires some care, because of the low melting point and the tenacious character of the oxide. The best welding is accomplished with a gas flame, but zinc also may be spot-welded electrically. Zinc cannot be welded without seriously weakening areas adjacent to the weld by annealing. If strength is important, some cold-working operation to refine the grain should follow welding.

Zinc tubing is made commercially by welding, followed by a drawing or swaging to a smaller diameter. It then has a uniform strength that approximates that of the rolled zinc from which the tubing is made.

**Soldering.**—Zinc is easily soldered. A low soldering temperature is necessary to avoid excessive grain growth in areas adjacent to the joint. This is best obtained by using a large iron, hot enough to accomplish the soldering with a single pass. Half-and-half solder generally is used, although a low-melting-point solder also is of advantage. A solder composed of Pb 55%, Sn 30% and Cd 15% is suitable for zinc. It has a low melting point and high tensile strength. Acidulated zinc chloride or killed hydrochloric acid makes an excellent flux, although much zinc is soldered without a flux.

**Hot Stamping.**—Certain complicated and deep draws, such as occur in ornamental sheet metal work, are made in heavy gage zinc by preheating the metal to about 480° F. before stamping. This work requires some knowledge of the working qualities of zinc at this temperature, and should be done by skilled workmen. For some uses, as in the manufacture of organ pipe, the zinc is given a thorough anneal prior to working. A 30-min. anneal at 480° F., while removing much of the desirable bending and drawing qualities, will reduce the metal to the very soft condition required for this use.

**Machining.**—In machining zinc it is common practice to use tools with a greater rake than normally is used, and to use soapy water as a lubricant.

**Plating.**—Articles produced both from die-cast and wrought zinc may be plated readily with any of the common plated finishes. Certain metals are absorbed by zinc, or present some difficulty in direct deposition. Nickel, therefore, commonly is used as a first coat and chromium or any other desired finish plated over it. A thickness of at least 0.0003 in. of nickel is considered necessary to good durability of plating for outdoor exposures.

**Paint and Baked Enamel Finishes.**—Sand blasting generally is recommended for preparing the surface of cast or rolled zinc for the application of any organic finish. Any finish used should be one properly formulated by the manufacturer to give good adherence on zinc. Baking enamels developed for use on zinc are designed to employ a low baking temperature.

# BRASS AND BRONZE

## 1. SAND-CAST, COPPER-BASE ALLOYS

**By W. M. Corse**

The alloys used by engineers and architects in the form of sand castings of bronze, red brass, yellow brass and white alloys containing more than 50% copper given in Tables 1 and 2, have been compiled from about twelve authorities. The values given are average and should not be used for specification limits. These results have been checked by Mr. Lewis H. Fawcett, Metallurgical Testing Laboratory, U. S. Naval Gun Factory, Washington, D. C.

**SELECTION OF ALLOY.**—The alloy which is suitable for any specific purpose is given in Table 1. The following notes cover the items which should be considered by the engineer in selecting and using cast copper-base alloys. Where corrosion resistance is of importance, the manufacturer of the alloy should be consulted as to its suitability under the proposed conditions, or tests made on samples of the alloy in question. The relative value of these alloys for mechanical purposes varies with temperature, and information on this point should be obtained before subjecting them to high-temperature use. The tensile properties of four copper-base alloys at high temperatures are given in Fig. 1.

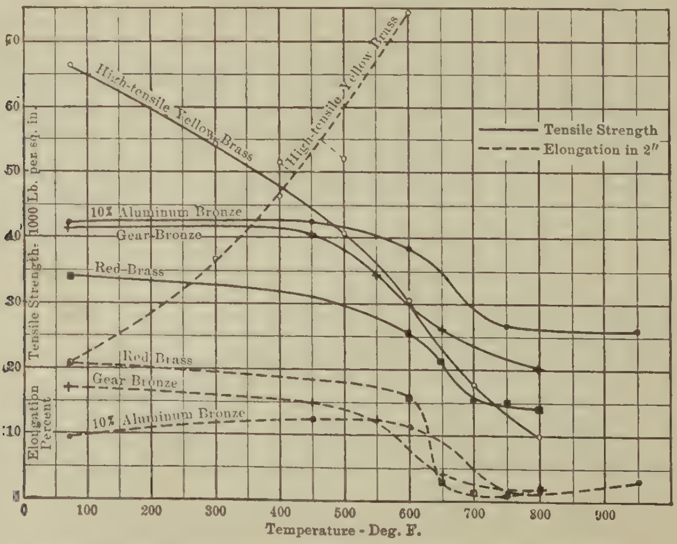

FIG. 1. Tensile Properties of Copper-base Alloys at High Temperature

**FABRICATION.**—Nearly all of the sand-cast copper-base alloys listed are readily machined. Some of the stronger alloys, such as aluminum-bronze and manganese-bronze are tough and difficult to machine, but with proper tool angles and machine conditions it is entirely possible to machine even these. These alloys as a class are not readily welded by any of the commercial methods. Their high heat conductivity dissipates the heat so rapidly that it is difficult to make a proper weld. The classes that can most readily be welded are the yellow brasses or manganese-bronze. The higher zinc content here seems to make welding commercially possible under many conditions.

**INSPECTION AND DEFECTS.**—The principal defects in castings, from an engineering standpoint, are shrinkage, blow holes, sand holes, and oxide inclusions. Shrinkage holes are usually found at a point where the heavy and light sections join. Blow holes are due to a faulty molding and melting condition, and sand holes are caused by imperfect

molding. Oxide inclusions may be caused by bad material but also, in some alloys, by excessive agitation during the pouring operation either inside or outside the mold.

**CORROSION.**—Certain alloys resist corrosion better than others, and in Table 2, under the heading "Remarks," this condition is noted in some cases. As a class these alloys are considered non-corrosive with reference to atmospheric conditions, but they vary widely when exposed to chemical agents. It is difficult to predict resistance to corrosion. In nearly every instance a trial is necessary to be certain.

**DESIGN OF CASTINGS.**—The design of castings is extremely important. It is well known that castings can be designed that are impossible to make in a foundry. The ideal casting is one which has a fairly uniform metal section with easy gradations from light to heavy parts. If engineers would keep this in mind in designing, much trouble would be saved the factory and the user. The variation in thickness in different parts of the same casting causes variations in strength, sometimes amounting to 50%. It is, therefore, impossible to predict exactly the strength of metal at any particular point in a casting without actually cutting a test piece from that point. As this usually is not practicable, standard test pieces are used as indicators. These test pieces are made under uniform conditions and show the properties of the alloy when cast in the best manner. From the results of mechanical tests of these test pieces specifications are drawn. If these specification values are used for comparison with results from test pieces cut from the castings of variable design a discrepancy usually will result. Frequently, engineers draw the conclusion that castings do not meet specification values. The error made here is in judging these results as comparable. The standard test piece indicates the quality of the material used, but the results from it should not be used to check values in the casting itself because of the variations noted above.

## 2. WROUGHT BRASSES, BRONZES AND NICKEL-SILVER ALLOYS

By W. H. Bassett *

The nomenclature used in the non-ferrous metals trade is confusing to those who are not familiar with the business, but through long usage it has become so thoroughly rooted that it is practically impossible to change it. The trade names have an actual value to the producers of various materials, and they would, therefore, naturally resist changes.

All questions of properties of engineering material are tied up with factors of safety, factors of reliability, conditions of exposure (which are always local) and similar matters. The requirements of special alloys for specific purposes may be considered from the viewpoint of the physical requirements or resistance to corrosion or both. The physical requirements and properties may be studied in the laboratory. The question of corrosion is less easily solved, due to the difficulty of reproducing in the laboratory the conditions to which the metal may be exposed in service.

The joint use of "dissimilar" alloys has caused much trouble. For instance, the use of one of the so-called "stronger brasses" (one of the brasses sometimes called bronzes which contains a considerable percentage of zinc together with tin or iron or a combination of these elements) in connection with a straight copper-tin bronze in an electrolyte such as sea water will result in the weakening of the alloy containing the larger proportion of zinc. Where brass strainers have been held in position with copper or gun-metal bolts and where brass screens have been placed in position with copper rivets, galvanic action has occurred, destroying the alloy containing the greater percentage of zinc.

Before proceeding with design, engineers not thoroughly familiar with the composition and properties of the alloys with which they propose to deal should consult reputable metallurgists, giving a thorough review of the conditions under which the material is to be used. The question of conditions of use is very important and should be carefully considered.

The so-called "season cracking" of brasses and bronzes has given much trouble in certain places. This phenomenon is due to the internal stress in the alloy brought about by cold working, such as rolling and drawing, and corrosive action. Copper and the copper-zinc alloys containing 20% or less of zinc are not subject to this trouble. The stronger copper-zinc alloys, as well as those containing tin and other elements, may be so prepared as to prevent this difficulty if the conditions of exposure are understood beforehand.

---

* This material was prepared originally by Mr. Bassett. After his death, Table 4 was revised by his associates, Messrs. H. G. Jennison and W. R. Hibbard.

Table 4 (p. 4–26) gives an idea of what may be expected in the way of physical properties from some of the more common combinations of metals, but should be used as a general guide only. Table 3 is an index to the alloys of Table 4.

Table 4 gives the more common wrought alloys with their ordinary physical properties, both "Hard Rolled" or "Drawn" and "Annealed" or "Soft." The figures are averages that ordinarily may be expected in practice but may be modified by "Extra Hard," "Half Hard" or "Quarter Hard" rolling. In other words, almost any physical properties between the figures for "Hard" and "Soft" may be obtained by appropriate working, and higher figures for tensile strength, or hardness, may be obtained by a greater amount of working. The alloys have been chosen to represent the more commonly used copper-zinc, copper-zinc-nickel, copper-tin and copper-aluminum mixtures. The alloys intermediate in composition between those chosen have physical properties lying between those given for the nearest compositions.

# ALUMINUM AND ITS ALLOYS

**By Zay Jeffries**

## 1. PROPERTIES OF ALUMINUM

Aluminum is one of the lightest of the metals used for structural purposes. The principal source of aluminum is bauxite, a hydrated oxide of aluminum, which is reduced to pure alumina, $Al_2O_3$, by treatment with caustic soda, from which the metal is obtained by electrolytic process. Impurities in the alumina, as silicon and iron oxide, will appear in the metal. Commercially pure aluminum contains from 99 to 99.5% aluminum, but grades containing 99.8% or more of aluminum are produced.

**CORROSION-RESISTANT CHARACTERISTICS.**—Aluminum is resistant to most atmospheric influences, especially inland industrial atmospheres. Paint or other protection, however, generally is advisable for permanent structures exposed to seacoast atmospheres. Examples of the resistance of unpainted aluminum and its alloys to atmospheric conditions are the relatively high-purity aluminum transmission lines and outside bus bar installations; aluminum-silicon alloy castings, used in large buildings as spandrels and other ornamental parts; wrought products, as window frames, store fronts and other parts of buildings. Aluminum is resistant to distilled water, many food products, fruit juices, milk and beer, and atmospheric nitric and glacial acetic acids. It is readily dissolved by hydrochloric and hydrofluoric acids, and caustic solutions.

The high corrosion resistance of aluminum is due to the protective effect of the oxide coating. In general, the highest purity aluminum has the highest corrosion resistance. Nearly all other metals present, either as impurities or alloying elements, tend to lower corrosion resistance. Manganese, chromium, and magnesium produce the most corrosion-resistant alloys. Silicon affects the corrosion resistance slightly, but it conveys other

beneficial effects, such as good casting characteristics. Therefore, it is either the major or one of the minor alloying constituents of many of the most corrosion-resistant alloys. Iron and copper lower the corrosion resistance, but properly heat-treated aluminum-copper alloys have sufficient corrosion resistance to be used for many applications without paint protection.

The thickness of an aluminum part has an important bearing on its ability to resist corrosion. Under corrosive conditions the rate of attack decreases with time, since the process of corrosion builds up a resistant film or coating which inhibits further attack. This action consumes some of the aluminum, and may result in complete perforation of thin sheet or foil, but in heavier sections the same amount of attack will have no appreciable effect on the mechanical integrity of the part.

In aircraft, the strong aluminum alloys are protected from corrosion by one of the several commercially available methods. Wrought Alclad products, consisting of a heat-treatable strong alloy core covered by a surface layer of high purity aluminum, or of corrosion-resistant alloy, combines mechanical strength and corrosion resistance. The surface layer covers the alloy core and so protects it from corrosion, and also, because of its higher solution potential, offers an electrolytic protection over cut edges and abraded areas, and prevents penetration into the core, even under severely corrosive conditions. Other non-heat-treatable Alclad products, employing the principle of a coating of higher solution potential than the core have high available resistance to destructive perforation.

Because of the high solution potential of aluminum and its alloys, contact with many of the commonly-used metals in the presence of a corrosive medium results in rapid deterioration of the aluminum, with a corresponding protection of the metal of lower solution potential. Hence, metallic contacts with other metals generally should be avoided. Electrical insulation between the two dissimilar metals is of value, although salts formed by the solution of the other metal may be plated out on the aluminum surface and set up electrolytic action. In spite of the rapid action in severely corrosive media, little corrosion occurs in ordinary atmosphere, unless a solution of relatively low electrical resistance accumulates. On the other hand, in some assemblies used in contact with strong electrolytes, it is even advisable to consider the relative solution potentials of various aluminum alloys which are in contact.

Exposure to the weather tends to darken and slightly roughen bright surfaces produced by rolling or extrusion, or highly polished surfaces. A bright, highly reflective surface may be maintained by periodic cleaning. Pitting of cooking utensils and similar articles, often is caused by plating out of particles of heavy metals which have been dissolved in the liquids being handled. This pitting can be avoided by regular cleaning.

**COMMERCIAL FORMS.**—Pure aluminum is soft and ductile but can be hardened by cold working and alloying; certain of the alloys also can be hardened by heat treatment. Both pure aluminum and its alloys are available in wrought form, as plate, sheet, rod, wire, tubing, and rolled and extruded sections. It also can be worked by forging, drawing, stamping, spinning, and other metal-working methods. Alloys are available in cast form, produced by sand, permanent mold, or die-casting processes.

## 2. CAST ALUMINUM ALLOYS

Pure aluminum does not cast easily, nor does such a casting have attractive commercial properties. The alloys of aluminum used for casting depend on the process employed, and are designated as follows: Sand cast alloys (Table 2); permanent mold casting alloys (Table 3); pressure die-casting alloys (Table 4).

**SAND CASTING.**—Large castings such as crank-cases for internal-combustion engines, oil pumps, manifolds, transmission housings, motor frames, architectural castings, etc., usually are made as sand castings. The ordinary methods of molding with green sand molds (see Foundry Practice, pp. 20–30 to 20–36) are employed, and good melting and patterns are necessary for the best results. Cores may be either green or baked sand, with binders of oil for hard cores, and pitch or resin for soft cores. Ample gates and risers are necessary. Cracks and shrinkage are avoided by the use of iron, aluminum or copper cores. Sand for molds must be of proper temper, and uniformly rammed. A hard-rammed mold is detrimental, as aluminum will not "lay" well against it.

**Melting.**—Iron pots, non-metallic crucibles or reverberatory furnaces generally are used for melting. The temperature preferably should be kept below 1500° F., and an oxidizing atmosphere is preferred to a reducing one. The metal must be stirred thoroughly to insure uniform composition. To obtain the strongest, most ductile and leak-proof castings, pouring temperatures should be the lowest at which the mold can be filled without misruns. Often the proper arrangement of gates and risers will facilitate the use of low pouring temperatures.

Hard spots which cause difficulty in machining, consist of foreign matter entrapped in the liquid alloys. They usually are the result of unclean melting practice.

**Maximum and Minimum Weights** range from 7000 lb. to as low as 1 oz. There is no inherent reason for weight limitations of sand castings.

**Section Thickness.**—Minimum section thickness of sand castings is about $^1/_8$ in. There is no maximum limit.

**Finish Allowance** on large sand castings ranges from $^3/_{16}$ to $^3/_4$ in., depending on design. For small bench-work castings, the finish allowance should be $^1/_8$ in. For disc grinding it should be $^1/_{32}$ in.

**Tolerances.**—Thickness tolerance on sand castings should be $^1/_{32}$ in. The weight tolerance with wood patterns should be $\pm 5\%$ and $\pm 3\%$ with metal patterns.

**PERMANENT MOLD CASTINGS** are poured in metal molds. Such castings are used for cooking utensils, vacuum sweeper and washing machine parts, cylinder heads, automobile pistons (made from the 122 or 132 alloy), etc. They may be made very close to size, and machine easily. As a result of the rapid chilling of the metal in the mold, the casting combines high hardness with toughness. Semi-permanent mold castings are made by using sand cores in conjunction with metal mold parts. This process gives great latitude in design, and at the same time gives the advantages of the permanent mold process.

**Maximum and Minimum Weights** of permanent mold castings range from 750 lb. to less than $^1/_2$ oz. The usual range, however, is from 20 lb. to $^1/_2$ lb.

**Section Thickness** should not be less than $^3/_{32}$ in., with no high limit.

**Finish Allowance** for permanent mold piston castings is as follows: Up to 3 in. diam., 0.075 in. on the diameter; up to 5 in. diam., 0.10 in.

**Tolerance.**—A dimensional tolerance of $\pm 0.010$ in. should be allowed. The weight tolerance with metal patterns should be $\pm 2\%$.

**PRESSURE DIE-CASTINGS** are made more nearly to size than either sand or permanent mold castings, with a consequent elimination of all or many machining operations. The die is filled quickly with metal under high pressure, and the casting solidifies so rapidly that crystallization shrinkage cannot be completely compensated, nor all of the entrapped air eliminated. The interior of the casting may be porous, but the outside shell usually is sound and strong. The average tensile strength of pressure die-castings is high, notwithstanding their porosity. Aluminum die castings may be made with thinner sections than castings made by other processes.

**Maximum and Minimum Weights.**—A pressure die-casting weighing 12 lb. is considered large. Castings as small as $^1/_2$ oz. are common.

### Table 2.—Composition and Properties of Sand-cast Aluminum Alloys *

| Alloy † | Nominal Chemical Composition | Tension,‡ Typical Values | | | Compression,¶ Typical Values | | Hardness, Typical Values | | Shear, Typical Values | Fatigue | Density |

* Modulus of elasticity approximately 10,300,000 lb. per sq. in. for these alloys.

† Alloy numbers, except A.S.T.M. and S.A.E., refer to alloys of Aluminum Co. of America. "T" suffix indicates heat-treated alloys.

‡ Tension values determined from standard 1/2-in. diameter tensile test specimens cast in green sand molds and tested without machining off the surface.

§ Stress at which stress-deformation curve departs 0.2 percent from the initial modulus line produced.

¶ Results of tests on specimens have an $l/r$ ratio of 16–20. All specimens failed by lateral bending.

‖ Single-shear strength values obtained from double-shear tests.

** Endurance limit based on 500,000,000 cycles, using R. R. Moore type of rotating-beam machine.

**Section Thickness.**—The minimum section thickness for pressure die-castings is about 1/8 in., with no maximum limit.

**Finish Allowance** is not required if tolerances of ±0.0025 in. are permitted.

**Tolerances.**—A dimensional tolerance of ±0.0025 in. should be allowed. The weight tolerance should be ±2%.

**ALUMINUM ALLOY CASTINGS AT HIGH TEMPERATURES.**—Strength and hardness of commercial aluminum decreases progressively with rising temperature. Certain alloys, however, are sufficiently strong and hard to be used commercially at high temperatures. Examples are pistons and cylinder heads of internal-combustion engines. See Table 5 for properties of such alloys.

One alloy is stronger at 600° F. than commercial aluminum at ordinary temperature. The values shown, however, for 400, 500 and 600° F. are much lower than those usually

**Table 3.—Composition and Properties of Permanent Mold Aluminum Casting Alloys**

* Alloy numbers referred to are those of the Aluminum Co. of America. Prefixed letters denote changes in composition of standard alloy. Suffixed "T" and number designate heat-treated alloys.

† Properties obtained from standard 1/2-in. diameter test specimens, individually cast in permanent molds and tested without machining off surface.

‡ Hardness limits are based on casting Brinell tests. In the case of 122 and 142 alloys, the Brinell is that obtained on the heads of permanent mold pistons 1/2 in. or less in thickness, and at a point 1/2 in. from outer edge and 1/2 in. from gate. For heavier castings, semi-permanent and sand-cast pistons, the hardness decreases proportionately with increased section, the maximum decrease being approximately 20.

**Table 4.—Composition and Properties of Aluminum-base Die-casting Alloys**

| Alloy Numbers* | Desired Composition, percent: Copper | Silicon | Nickel | Aluminum | Typical Values: Tensile Strength, lb. per sq. in. | Elongation, % in 2 in. |
|---|---|---|---|---|---|---|
| IV | ........ | 5 | ........ | 95 | 29,000 | 3.5 |

‡ Elongation, percent in 2 in.
§ Brinell hardness at room temperature after stabilization and testing at elevated temperatures.
‖ Properties after 18 days at temperature; not completely stabilized.

associated with such temperatures, because of the stabilization of the alloys at the test temperature prior to the test itself.

Except for the values given at 500° F. for 132 alloy, the minimum time of exposure at test temperature prior to testing was 75 days. The effect on the material is indicated by the hardness values, which were determined at room temperature after the test piece had been stabilized at the test temperature. For example, the room temperature hardness of the 132 alloy changes from 130 to 54 by holding at 600° F. for 75 days.

For the properties of aluminum alloys at elevated temperatures, see R. L. Templin and D. A. Paul, The Mechanical Properties of Aluminum and Magnesium Alloys at Elevated Temperatures, in Symposium on Effect of Temperature on the Properties of Metals, issued jointly by A.S.T.M. and A.S.M.E., 1931.

## 3. WROUGHT ALUMINUM ALLOYS

**CLASSIFICATION.**—Aluminum wrought alloys may be classified as: 1. Alloys in which various tempers are produced by cold working; 2. "Strong alloys" or those in which the desired properties are obtained by heat treatment, and which in general have higher mechanical properties than those of (1).

Table 6 gives the composition and Table 7 the specific gravity and weight of commercial wrought alloys. The designating number indicates the composition. The suffix S indicates that the alloy is wrought or capable of being wrought.

**Temper** is designated by a suffix following the alloy designation, as follows: Soft or annealed alloys, suffix –O; hard temper, suffix –H; for intermediate cold-worked temper, a fraction precedes the suffix H. For example, 3S – $^{1}/_{2}$H indicates alloy 3S, half-hard temper. Tempers produced by cold working are defined by the tensile strengths of the products, rather than by the amount of reduction during fabrication.

* Duralumin.

**Heat Treatment Designation.**—Strong alloys in which the maximum strength has been developed by a solution heat treatment, *i.e.*, heating to the proper temperature, quenching in cold water, and aging, are designated by the suffix —T.

Some strong alloys age at room temperature. Others must be subjected to higher temperatures to precipitate certain constituents. These latter alloys are designated 25S–W, 51S–W, 53S–W, and C17S–W when they have been quenched and not subjected to precipitation treatment, although 51S–W and C17S–W will age somewhat spontaneously at room temperature.

The strong alloys have lower mechanical properties and may be subjected to more difficult forming operations before aging, than when they are in the fully heat-treated "T" condition. Since the alloys which age at room temperature do not acquire the full properties of the "T" condition until about four days have elapsed after quenching, the practice of forming, particularly driving 17S rivets, immediately after quenching frequently is followed. Room temperature aging also can be effectively retarded by holding the material at a low temperature after quenching. This can be accomplished by packing in ice or in solid carbon dioxide (dry ice).

The suffix –RT indicates alloys that have been cold worked after heat treatment, by an amount carefully controlled to retain suitable ductility in the product. Such treatment produces in some alloys higher yield strengths than are obtained by heat treatment alone.

**MECHANICAL PROPERTIES.**—Table 8 gives the mechanical properties of wrought aluminum alloy sheet. These properties are generally applicable to all products, except that the elongation depends somewhat on the size and shape of test specimen. In certain products, as heavy bar and plate, the reduction may not be sufficient to develop the maximum properties of the alloy on subsequent heat treatment.

**EFFECTS OF COLD WORKING.**—Many commercial wrought products of aluminum and its alloys are supplied in various tempers determined by the amounts of cold working given the products after final annealing. See R. L. Templin in The Aluminum Industry, vol. II, chapter xix, p. 396, and the A.I.M. & M.E., Institute of Metals Division, p. 466, 1930, for a discussion of the effect of cold working on the physical properties of aluminum and its alloys. The formulas and diagrams below are taken from these references.

Cold working is defined as the change in cross-sectional area of the metal resulting from rolling, forging, drawing, or extrusion at about room temperature, *i.e.*, 60 to 80° F. Generally, change in cross-sectional area of the metal amounts to a reduction in area. In rolling wide sheet, a reduction in cross-sectional area of the product may be considered as resulting solely from the reduction in thickness of the product.

If aluminum and its alloys be worked at temperatures above room temperature, the effects of cold working are less in proportion to the amount of work done than when they are worked at room temperature. Conversely, the work done at temperatures below room temperature is more effective than the same amount of work at room temperature.

Cold working is expressed as the percentage change in the original cross-sectional area (commonly called *reduction*) as follows:

In general, $C = 100\ (A - a)/A$, where $C$ = amount of cold working, percent; $A$ = initial area of material in properly annealed condition; $a$ = area of the cold worked material.

For sheet, $C = 100\ (t_o - t_f)/t_o$, where $t_o$ = initial thickness of the material and $t_f$ = final thickness.

The effect of cold working on the tensile strength of wrought aluminum and its alloys is shown by $\text{T.S.} = \text{T S.}_o(1 + 0.9R)$, where T.S. = tensile strength in lb. per sq. in.; $\text{T.S.}_o$ = tensile strength of the properly-annealed material; $R$ = reduction in area expressed as a decimal.

The average tensile strength of the annealed commercial alloys which are fabricated into products of various intermediate tempers by cold working are as follows:

| Metals or Alloys | 2S–O (Pure Al) | 3S–O | 4S–O |
|---|---|---|---|
| Tensile strength, lb. per sq. in. | 14,000 | 15,500 | 26,000 |

| Wire | 0 | 1 | 2 | 4 | 7 |

* Percent reduction in cross-sectional area.

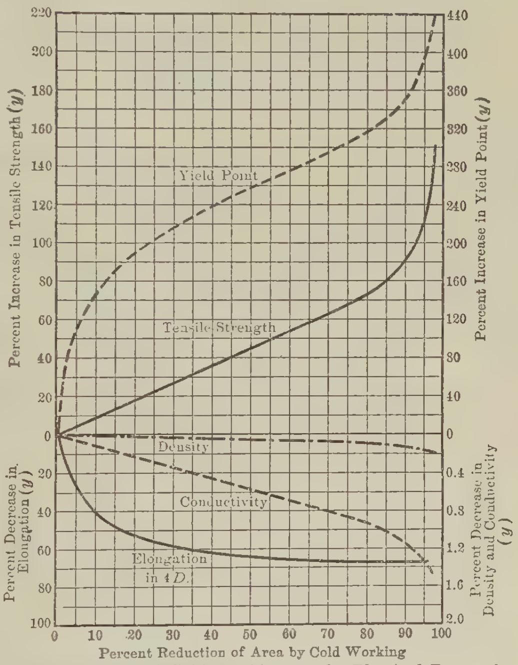

FIG. 1. Effects of Cold Working on the Physical Properties of Aluminum

Table 9 gives the nominal amounts of cold working together with the approximate Brown & Sharpe gage numbers reduction for the various tempers.

The yield strength of aluminum and its alloys is the stress corresponding to a limiting permanent set of 0.2%. In properly-annealed wrought metal this value will be approximately one-third of the ultimate tensile strength. For all of the other tempers of a cold-worked product, the yield strength will vary from 80 to 95% of the ultimate tensile strength.

Elongation is affected considerably both by the size and shape of the test specimen, as well as by the ductility and elongation.

The relation between tensile strength and Brinell hardness of wrought aluminum and its alloys is approximately T.S. = 755 × Brinell hardness number.

Fig. 1 shows graphically the effects of cold working on the physical properties of aluminum and its alloys.

**COLUMN FORMULAS.**—The following formulas may be used in the design of columns of aluminum subjected to axial loads:

$$\text{Round Ends}\begin{cases}\text{For } L/r \text{ values of 0 to } C, & f = B - K(L/r)\\ \text{For } L/r \text{ values of } C \text{ and up} & f = 33{,}000{,}000/(L/r)^2\end{cases}$$

$$\text{Fixed Ends}\begin{cases}\text{For } L/r \text{ values of 0 to } C & f = B - K(L/r)\\ \text{For } L/r \text{ values } C \text{ and up} & f = 132{,}000{,}000/(L/r)^2\end{cases}$$

where $f$ = safe design stress in axially-loaded column, lb. per sq. in.; $L$ = unsupported length of column, in.; $r$ = least radius of gyration of column, in.; $L/r$ = slenderness ratio of column. Values of $C$, $B$ and $K$ are given in Table 10.

**Table 10.—Values of Constants for Column Formulas**

| Alloy and Temper | Round Ends | | | Fixed Ends | | |
|---|---|---|---|---|---|---|
| | *C* | *B* | *K* | *C* | *B* | *K* |
| 3S–1/2 H | 128 | 6,000 | 31 | 256 | 6,000 | 15.5 |
| 3S–H | 111 | 8,000 | 48 | 222 | 8,000 | 24 |
| 4S–O | 128 | 6,000 | 31 | 256 | 6,000 | 15.5 |
| 4S–1/2 H | 100 | 10,000 | 67 | 200 | 10,000 | 33.5 |
| 4S–H | 87 | 13,000 | 100 | 174 | 13,000 | 50.0 |
| 17S–T | 81 | 15,000 | 123 | 162 | 15,000 | 61.5 |
| 51S–W | 105 | 9,000 | 57 | 210 | 9,000 | 28.5 |
| 51S–T | 84 | 14,000 | 111 | 168 | 14,000 | 55.5 |

**DESIGN STRESSES FOR ALUMINUM ALLOYS.**—In Table 11 are given the stresses considered safe for ordinary structural design at temperatures below 100° F. Where temperatures above that point are to be considered, the values in Table 11 should be multiplied by the factors in Table 12.

**Table 11.—Design Stresses for Aluminum Alloys**

Applicable to temperatures below 100° F.

| | Alloy and Temper | Tension, lb. per sq. in. | Compression, lb. per sq. in. | Bearing, lb. per sq. in. | Shear, lb. per sq. in. |
|---|---|---|---|---|---|
| Wrought | 3S–O | 4,000 | 4,000 | 7,000 | 3000 |

## 4. HEAT TREATMENT OF ALUMINUM ALLOYS

**SOLUTION HEAT TREATMENT.**—A change in properties as a result of heat treatment of aluminum alloys usually is associated with a change in solubility of one or more of the alloying ingredients with change in temperature. Thus, over 5% copper is soluble in solid aluminum just below the melting point of the eutectic; at room temperature the solubility is well below 1%. If aluminum alloys containing 4% or more of copper be heated to a temperature slightly below the melting point of the eutectic, the copper will dissolve in the aluminum at that temperature. If the alloy then be cooled quickly to a low temperature, it becomes supersaturated in copper at the lower temperature. This treatment is known as a solution heat treatment. In certain alloys, like 17S or duralumin, the supersaturated solid breaks down at ordinary temperatures. This change, known as aging, changes the physical properties.

In carrying out the solution heat treatment, temperature must be closely controlled. Thin pieces of wrought metal may be heated to the proper temperature and held there only a short time before cooling, with good results. The operation may be carried on in a hearth or pit furnace or in a bath of fused niter. Castings and large wrought pieces, however, must be held at the solution heat treating temperature for considerable periods of time, and automatic temperature control practically is necessary. Cooling, after the proper heating cycle, may be done in cold or hot water, oil, or an air blast.

**PRECIPITATION HEAT TREATMENT.**—In certain alloys, the changes produced at ordinary temperatures are insufficient for the requirements, and the desired results are effected by elevated temperatures. Such a treatment is known as the precipitation heat treatment, or artificial aging. In general, aging will increase hardness and strength of aluminum alloys. The same is true of the precipitation heat treatment, if it is not carried too far. The latter, assuming prior solution heat treatment, is capable of producing a wide range of properties without change in the alloy composition.

The precipitation heat treatment may be effected by heating in pressure vessels with steam, or by heating in baths such as oil, or in hearth or pit furnaces. The temperature should be well controlled for best results, and if an ordinary furnace is used, air circulation is desirable. The rate of cooling after the precipitation heating usually is not an important factor.

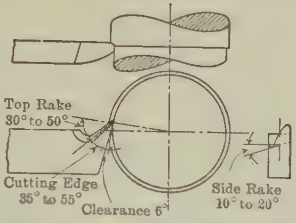

Fig. 2. Lathe Tool That May Be Used with Aluminum

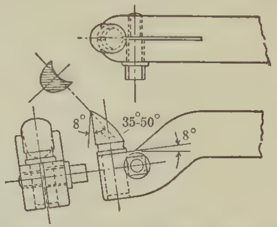

Fig. 3. Lathe Tool Recommended for Use with Aluminum

**OTHER EFFECTS OF HEAT TREATMENT** of aluminum alloys are the removal of internal strains, stabilization of dimensions of parts used or processed at elevated temperatures, and change in particle size of constituents such as silicon, which may be present in amounts greater than can be dissolved in solid aluminum even at the eutectic temperature.

## 5. FABRICATION OF ALUMINUM

**FORGING.**—Several of the strong aluminum alloys may be forged hot either under a hammer or in a forging press. Alloy 25S T is used for general forgings including connecting-rods, aircraft propellers and crank-cases, because of its superior hot working characteristics. Alloy 51S–T is used for crank-cases and nose pieces of more intricate design for radial aircraft engines, since this alloy is even more easily forged into the large thin sections. For a more limited class of forgings 17S also is used. Forged pistons are commonly manufactured from 32S which has a low coefficient of expansion, or from 18S.

**MACHINING.**—Aluminum and its alloys may be machined readily. In many instances, satisfactory results may be obtained by using tools ordinarily used for steel, provided they are sharp and in good condition. Owing to its inherent machining characteristics, better results may be obtained, however, when certain changes in tool shape and machining practice are observed. Generally speaking, aluminum and most of its alloys have familiar machining characteristics.

Cutting tools for aluminum resemble those for cutting hard wood in many respects. It should be emphasized that the cutting edges must be ground to a sharp included angle, must be keen, and should be provided with smoothly finished surfaces. The tools generally are ground with fine abrasive wheels, supplemented by hand stoning with an oilstone to give the desired finish of the surfaces and edges.

**Lathe, Shaper and Planer Tools.** Figs. 2–5 illustrate typical lathe and planer tools for machining aluminum. Attention is called to the unusually large amount of top and side rake.

**Milling Cutters** for aluminum should be of the coarse-tooth spiral type, with a considerable amount of top rake on the cutting edges. The more recent helical milling cutters, designed primarily for machining steel, work especially well with aluminum and its alloys, if the cutting edges are provided with suitable top rake.

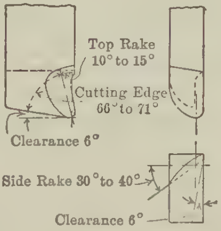

Fig. 4. Planer Tool for Roughing Aluminum

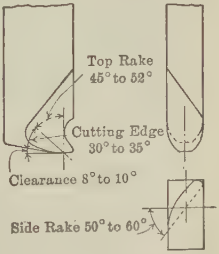

Fig. 5. Planer Tool—Finishing

**Drills.**—Ordinary twist drills work fairly satisfactorily in aluminum if properly ground with keen edges, but a better type of drill is one with more twist to the flutes.

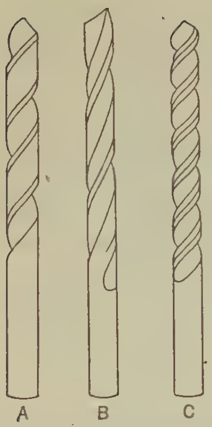

FIG. 6. Three Types of Twist Drills, $^3/_8$ in. diam.

*A*, Single flute twist-drill, 40° spiral angle
*B*, Double flute or standard twist-drill, 24° spiral angle
*C*, Special double fluted twist drill, 47° spiral angle

Both types are illustrated in Fig. 6. Fairly high speeds may be employed if ample cutting compound is used.

**Reamers** of the spiral fluted type produce the best results for reaming holes in aluminum.

**Taps** generally designated "gun" taps or spiral pointed taps, Fig. 7, which have a short spiral ground at the nose, work very satisfactorily in aluminum, especially for through holes where the cuttings can be pushed ahead. Better results may be obtained by the use of spiral fluted taps, now offered by a number of the manufacturers of small tools.

**Sawing.**—The shapes of saw teeth should be patterned after those of the cutting tools described above, so far as practicable. Teeth usually should have some top rake or hook, the amount depending on the type of saw, although very little can be used with band saws or circular saws where the work is fed by hand. The teeth should be comparatively coarse, with curved gullets, free from sharp corners and burrs or scratches which are apt to pick up cuttings.

Circular saws for aluminum may be operated at peripheral speeds of about 10,000 ft. per min. Speeds of about 5,000 ft. per min. are recommended for band saws. It is important that the machine be free from vibration, otherwise fatigue failure of saw blades or saw teeth will ensue.

A cutting lubricant or coolant is desirable, and for heavy work is necessary. Mineral-base lubricating oils thinned with kerosene and, in some instances, soluble oil cutting compounds have been found satisfactory.

Hand hack-saw blades of the "wavy-set" type work especially well with aluminum.

**Files.**—Some of the coarse-tooth files with top and side rake to the cutting teeth work well on aluminum.

**Cutting Speeds and Feeds.**—A wide range of cutting speeds and feeds may be used in machining aluminum and its alloys. Roughing cuts may be quite heavy. For highly finished surfaces, cuts only a few thousandths of an inch deep may be used, provided the cutting tools are properly shaped and finished. Speeds necessarily depend on such factors as the kind of machining operation, type and condition of machine tool and kind of cutting material. Cutting speeds faster than those ordinarily used for free-cutting brass have been used with success in some instances, while in others better results have been obtained by using slower speeds.

**Cutting Lubricants.**—Some of the alloys of aluminum have been machined successfully without any lubricant or coolant, using tools of the form described, but the use of some form of compound is desirable for best results. The soluble cutting oils usually are satisfactory for milling, sawing, and drilling. For such operations as turning, shaping, and tapping, a mixture of equal parts of lard oil and kerosene generally is recommended. Cutting compounds of paraffin oil, such as are used in machining brass, are not satisfactory for aluminum.

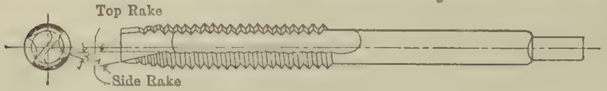

FIG. 7. "Gun" Tap

**Tool Materials.**—Tools for machining aluminum may be either of high-carbon or high-speed steel. Cemented tungsten-carbide tools have been found indispensable, especially for machining aluminum alloys with high silicon content; they also are excellent for high production.

## 6. JOINING OF ALUMINUM

**WELDING.**—Aluminum and its alloys may be welded by the torch, electric arc or resistance processes. In fusion welding, the equipment is the same as that used for welding steel, but in electrical resistance welding, machines of slightly different design and greater electrical capacity are required. The technique varies slightly from that required for steel. The metal arc generally will make stronger welds than can be made with the torch, but $^1/_{16}$ in. is the minimum thickness of metal that can be so welded.

For metal arc electrodes, and for filler rod for torch welds of strong alloys, an alloy of 5% Si, 95% Al is used. For torch welds of common alloys, as 2S and 3S, especially if a polished surface is desired, pure aluminum filler rod is used. A flux is used in fusion welding. In the metal arc process, the flux is best applied as a heavy coating on the electrode.

A welded joint, except in fully-annealed material, will have lower mechanical properties than those of the unwelded metal. The heat of welding has an annealing effect on the common alloys, and a somewhat deleterious heat treating effect on the strong alloys. In some cases, it also affects adversely the corrosion resistance. Heat treatment of strong alloy welds will improve the properties of the joint. If maximum efficiency of the joint is to be developed, a well-designed mechanical joint is superior to torch welds, and often superior to arc welds.

**SOLDERING** of aluminum is more difficult than the soldering of other non-ferrous metals. With ordinary soldering technique, oxide film on aluminum prevents wetting the metal. Many solders fail to make corrosion-resistant joints when applied to aluminum. However, there are available a variety of solders and fluxes adapted to nearly all soldering requirements. The use of the proper solder and flux enables aluminum parts to be joined in much the same way and for about the same type of service as soldered joints of other metals. Suitable directions can be obtained from the supplier of solder and flux.

**RIVETING.**—In general, the alloy used for rivets for aluminum alloy structures is the same as that of the structure, if sufficient strength may be obtained in this way. When greater strength is needed, rivets are made from stronger alloys than the rest of the structure; sometimes steel rivets are used.

Aluminum alloy rivets should be driven cold, where this is possible. Rivets of non-heat-treated alloys, as 3S and 4S, and some of heat-treated alloys, as 51S–W, are ready for driving when received from the maker. Heat-treated alloy rivets, as 17S, which are too hard to drive satisfactorily when fully heat-treated (T temper) and which do not have any stable intermediate temper (W temper), must be heat-treated immediately before driving. The treatment consists of heating to a temperature of 940 to 960° F. and quenching in cold water. For about 2 to 4 hours after quenching, the rivets are soft enough to be driven with comparative ease. Rivets so driven become fully aged in about 4 days, after which they exhibit the properties of 17S–T alloy. Most of this aging takes place in the first day, which accounts for the difficulty of driving after the lapse of 2 to 4 hours after quenching. Rivets that become too hard to drive may be re-heat-treated. The rate of hardening of 17S alloy rivets may be retarded by storing the quenched rivets at low temperatures. Temperatures of 32° F., for example, will keep the rivets soft enough for driving for at least 24 hours. Electric refrigeration or dry ice may be used to maintain even lower temperatures, with a resulting substantial decrease in the rate of hardening.

Strong aluminum alloy rivets up to $^3/_8$ in. may be driven cold, but cold driving of larger sizes is almost impossible, unless large squeeze riveters are available. Hot-driven rivets should be heated to heat-treating temperature (940 to 960° F. for 17S) and driven with a minimum of delay. The contact of the rivet with the relatively cold material around the hole provides a quench. Rivets as large as 1 in. have been driven successfully in this manner, and the properties of the material are practically as good as water-quenched material. In hot driving the heating equipment must have exact temperature control and be close to the work. In general, the squeeze method is best for driving aluminum alloy rivets. If pneumatic hammers are used, they should be of large size, as a few heavy blows are superior to a number of light, rapid blows.

Steel rivets are used in aluminum alloy structures only when the heating effect is of no consequence, and rusting may be prevented. Then the relatively large shear strength of steel rivets, coupled with the ease of driving, makes them very desirable. The procedure for driving hot steel rivets in aluminum alloy structures is the same as for steel structures, except that it is advisable to drive the rivets at random in order to avoid localized heating.

**Rivet Holes** in aluminum may be drilled, punched, or sub-punched and reamed as desired. When holes are drilled or sub-punched and reamed, the diameter of the hole generally is made $^1/_{32}$ in. greater than the diameter of the rivet. For heavier work, where holes are punched, the hole generally is made $^1/_{16}$ in. greater in diameter than the rivet. Taper bridge reamers with spiral flutes are recommended for reaming sub-punched holes to size.

## 7. FINISHING OF ALUMINUM

**FROSTED FINISH** usually is applied to aluminum by etching in a hot solution of sodium hydroxide (caustic soda) followed by treatment with strong nitric acid. For ordinary operations, the solution contains from 2 to 5% of caustic soda, although solutions containing as much as 25% are used. The time of immersion is determined by the temperature of the solution, its concentration, and the depth of etch required. Usually treatments of about one minute are sufficient.

After removal from the caustic solution, the object is rinsed in clear water and immersed in strong nitric acid. A satisfactory solution is two parts concentrated nitric acid and one part water. Occasionally, a weaker solution, say 10% to 15% nitric acid, may be used. The nitric acid has little solvent action on the aluminum, but removes the colored film left on the surface by the caustic dip and leaves the metal with a clean "frosted" finish.

**ELECTROPLATING.**—Aluminum may be electroplated with other metals. Such plating is used primarily for ornamental reasons rather than as a protection against corrosion. The aluminum surface first is roughened by special etching procedures, which depend on the alloy being coated, to provide a firm anchorage for subsequently-applied nickel plating. Once the nickel has been properly applied, any desired metal may be plated over it. Zinc applied directly to the aluminum surface will electrochemically protect the aluminum. Chromium directly applied will resist abrasion or chemical attack by mild alkalis.

**OXIDE COATINGS.**—The electrolytic or anodic oxide coating process, sometimes known as deplating, is carried out in a special electrolyte in which the piece to be finished is immersed as the anode (positive electrode). Applied to aluminum and many of its alloys, it forms a hard, abrasion-resistant coating of superior protective value. It usually is white to light gray in appearance, but on aluminum-silicon alloys it forms a dark gray coating, which is of artistic value, particularly on sand blasted castings. The electrolytic oxide coating also may be given marked absorptive properties, which permit its being colored by dyes and pigments. They combine the luster and brilliance of the metal with the color of the dye, which is highly attractive.

**PAINTING AND LACQUERING.**—Aluminum may be coated with paint or lacquer by much the same technique as followed for other metals. Surface preparation is important. Normally, all that is required is a cleansing from grease and dirt by wiping the surface with mineral spirits or other solvent. Certain chemical cleansing agents, as a phosphoric acid-alcohol mixture, sold under various trade formulas, not only clean the surface but give greatly improved paint adhesion where service conditions are severe. With castings, a light sand blast improves adhesion of paint. Sheet or extruded shapes, with either an electrolytic or chemical oxide coating, provide exceptionally good adhesion, especially in painting for protection against salt water corrosion.

Paint in the form of aluminum paint, oil-base enamels or lacquers, may be applied by spraying, brushing, or dipping. Synthetic resin varnishes and enamels materially increase the durability of such finishes. Except under severe exposure conditions, such as on aircraft, a special priming coat on aluminum surfaces is unnecessary. Where extra protection is desired, a priming coat containing zinc chromate pigment is effective.

Transparent varnishes or lacquers may be used to preserve polished surfaces. Many of these are sufficiently durable to be applied to exterior ornamental work. A varnish of light color and one which is relatively insensitive to light exposure, should be selected. Synthetic resins have increased durability; no clear finish, however, will last as long as pigmented finishes.

**Aluminum Paint** is made by mixing aluminum-bronze powder with a suitable vehicle. Aluminum-bronze powder is supplied either as a dry powder or as a paste mixed with mineral spirits. Aluminum paint, in the proportion of two pounds of powder to a gallon of vehicle, forms a coating of high moisture resistance and superior protective qualities. By proper choice of vehicle it can be used on metal, wood, plaster, or concrete, and is particularly recommended for the painting of aluminum and its alloys.

**POLISHING.**—Aluminum in any form can be polished or buffed. The degree of polish depends on the hardness and freedom from porosity of the metal. Thus, a piece of hard-rolled sheet will take a more brilliant polish than a soft casting. Polishing may consist of four steps, although if the surface is already quite smooth, as in a cooking utensil made from sheet, only the last two operations may be necessary. See also pp. 21–88 to 21–96.

**1. Roughing (Canvas or Rag Wheel).**—The wheel is made of sewed buffs, glued together. The polishing head, of No. 60 to No. 100 emery or silicon-carbide abrasive, is glued to the face of the wheel, which should have a peripheral speed of about 6,000 ft. per min. A lubricant consisting of polishing oil and tallow generally is used, the surface of the article being smeared with lubricant during the operation.

**2. Oiling.**—A solid felt or compress canvas wheel, with a polishing head of No. 100 to No. 160 emery or silicon-carbide abrasive glued to the face, is used. The same lubricant as for roughing is used, applied to the wheel.

**3. Buffing.**—The buffing wheel is made up of sewed-piece or full disc packed buffs. The full disc buffs should be a close weave, say 84 × 92. The shape of the wheel is determined by the shape of the work. Tripoli composition is satisfactory for polishing aluminum. The peripheral speed of buffing wheels generally is 7000 to 7500 ft. per min. After buffing, the work is cleaned in benzine and dried in sawdust.

**4. Coloring** is best done with a full disc buff or one of the varieties of patented folded buff. Tripoli, rouge, and soft silica compositions are used to bring out the silvery white color of aluminum.

**SCRATCH BRUSH AND SATIN FINISH.**—Aluminum can be so finished as to diffuse the rays of light, producing a surface similar in appearance to frosted or etched glass. These finishes, produced by the use of a rotating wire brush, are called "Scratch Brush" or "Satin" finish. A scratch brush finish may be done in a large lathe, using a soft steel-wire brush, about 10 in. outside diameter, revolving about 2000 r.p.m. The wire size is about 0.015 in. diameter. A satin finish, of finer texture, is produced, using wire brush wheels with wires about 0.005 or 0.003 in. diameter. A satin finish also may be obtained by means of a buffing wheel, using Lea greaseless compound and Learock on the wheel. See booklet, Buffing and Polishing Methods, issued by the Lea Mfg. Co., Waterbury, Conn.

**SAND BLAST FINISH** frequently is applied to castings. It is of varying degrees of fineness, depending on the nature of the work and the ultimate finish desired. The use of coarse sand is satisfactory for surfaces which are to be oxide coated, but is somewhat limited in its use because of its heavy abrasive action, resulting in excessive warpage of large thin sections. The finer sizes of sand are used for high-lighted and satin-finished work, since their milder abrasive action reduces the subsequent cost of grinding and polishing.

## 8. FABRICATED ALUMINUM PRODUCTS

**SHEET AND PLATE.**—Plate can be supplied up to 2 in. thick, with a maximum weight limitation of 2000 lb. per individual plate. Sheet from No. 10 to 36 gage also can be supplied in coils. Tables of commercial sizes of sheet and plate are given on pp. 6–08 to 6–12.

**TUBING.**—The operations which are necessary to straighten 17S–T tubing, after it has been quenched, increase the yield strength by about 25% as compared with the value normally obtained in commercial sheet. Tubing in round, square, and streamline cross-section also is produced in 17S–RT, having a yield strength approximately 30% higher than that of 17S–T tubing, and about 60% higher than that of 17S–T sheet. If these materials are heat-treated by the user, yield strengths comparable to those of 17S–T sheet will be obtained. Tubing also is available in other shapes, such as rectangular, hexagonal, octagonal, streamline, and odd shapes.

**STRUCTURAL SECTIONS.**—Aluminum is rolled into various structural shapes, as beams, channels, angles, tees, zees, and streamlined shapes. For dimensions and properties, see pp. 6–12 to 6–16.

**WIRE, ROD, AND BAR** are available in a wide variety of sizes and shapes. Wire is produced by drawing from large rod sizes to the desired dimensions; flattened wire by rolling round wire to produce a strip with round edges; flattened and slit wire and strip are produced by rolling a round wire or a rectangle to the desired width to produce a strip with square edges. Round wire is made in sizes from No. 00 B. & S. gage to 38 gage, and round rod up to 8 in. diameter.

**ALCLAD PRODUCTS,** in sheet or wire, consist of surface material of exceedingly high corrosion resistance, alloyed and integral with a strong alloy core. The thickness of the surface metal is such as to retain maximum physical properties consistent with adequate protection of the core. The coating protects the alloy which it covers, and also electrolytically protects exposed edges, or base alloy which may be exposed by scratches or abrasions. It also protects 17S rivets, which are used to join Alclad sheet.

**ALUMINUM FOIL.**—Aluminum sheet 0.005 in. and less in thickness is termed foil. Foil may be rolled commercially to gages as thin as 0.00025 in., but thicknesses of 0.0003 to 0.0007 in. are commonly used. For these extremely thin gages a special grade of pure metal is used. Where additional strength is required, as for diaphragms and shims, and other purposes, alloys of aluminum are used. Alloy foils, however, being less ductile, usually are 0.001 in. thick and heavier.

Aluminum foil is used widely in electrolytic condensers for radio equipment, power factor condensers, etc., because of its film forming characteristic. It also is used in foil and paper type condensers, in contacts for burglar alarm systems, protecting tape for underground cables, etc. Aluminum foil, either plain or backed with waxed paper and lacquered or printed in colors, is used for articles which must be protected from the atmosphere or from handling, including photographic films, friction tape, typewriter ribbons, etc. Its non-toxic quality has resulted in its being used extensively for wrapping food

**Table 13.—Aluminum Foil**

| Thickness | | Area, sq. in. per lb. | Thickness | | Area, sq. in. per lb. | Thickness | | Area, sq. in. per lb. |
|---|---|---|---|---|---|---|---|---|
| in. | mm. | | in. | mm. | | in. | mm. | |
| 0.00025 | 0.00635 | 41,000 | 0.0006 | 0.01524 | 17,000 | 0.0015 | 0.03810 | 6800 |
| .0003 | .00762 | 34,100 | .00065 | .01651 | 15,700 | .0020 | .05080 | 5100 |
| .00035 | .00889 | 29,200 | .0007 | .01778 | 14,600 | .0025 | .06350 | 4100 |
| .0004 | .01016 | 25,600 | .0008 | .02032 | 12,800 | .0030 | .07620 | 3400 |
| .00045 | .01143 | 22,700 | .0009 | .02286 | 11,400 | .0040 | .10160 | 2550 |
| .0005 | .01270 | 20,500 | .0010 | .02540 | 10,250 | .0050 | .12700 | 2050 |
| .00055 | .01397 | 18,600 | ...... | ...... | ...... | ...... | ...... | .... |

products. It also is used in the manufacture of artificial flowers, light-bulb reflectors, box wrapper and liners, labels, can liners, bottle caps and cap liners, magazine and book covers. Aluminum foil is regularly supplied in coils or in rectangular form. It may be paper interleaved, wax paper backed, or cement or asphalt paper mounted, embossed, printed, or lacquered in standard or special colors or designs.

Foil thinner than 0.001 in. does not permit accurate measurements of thickness by a micrometer. Gages thinner than 0.001 in. are determined by weighing a sample of foil of a known area and calculating the thickness, using the value of 2.70 as the density of aluminum. Covering area in square inches per pound of foil for foil gages 0.005 in. and lighter are given in Table 13.

## 9. ELECTRICAL USES OF ALUMINUM

Aluminum was first used as a conductor in high tension wires in the U. S. in 1898. The first conductors were made entirely of aluminum, but later a cable with an extra high strength steel reinforcing core for the aluminum strands was developed and has since been used with marked success.

**CONDUCTIVITY.**—The A.I.E.E. standard of conductivity for hard drawn aluminum wire is 60.97% of the International Annealed Copper Standard. On this scale the conductivity of commercial hard-drawn copper usually is taken at 97%.

The electrical conductivity of annealed high-purity (99.97%) aluminum is 64.6%, based on the International Annealed Copper Standard. The electrical conductivity is lowered by the addition of alloying elements, the reduction varying with the nature of the element and the amount added. Heat treatment and mechanical working also influence this property to a marked degree. The following are the approximate conductivities of various grades of aluminum and aluminum alloys:

| Metal............ | 99.97% Al | Hard-drawn Conductors | 2S–O | 3S–O | 3S–H | 17S–T | 25S–T | 51S–T |
|---|---|---|---|---|---|---|---|---|
| Conductivity, percent of Int. Annealed Copper Std...... | 64.6 | 61 | 57 | 50 | 40 | 30 | 35 | 45 |

**CABLES AND CONDUCTORS.**—Aluminum cable, steel-reinforced, is used for messenger cables of overhead catenary railway lines. In the smaller sizes, it also is used for signal circuits, and for telephone lines supported on the same structure with power lines, where its high strength permits the use of as long spans as the transmission conductors. Large all-aluminum cables have been used as railway feeders, where they carry heavy currents at relatively low voltages. Particularly in large conductors, the use of aluminum effects a great saving in weight. Conductors for high-voltage installations such as outdoor sub-stations may advantageously be made of aluminum tubing. These are rigid and light, and permit the use of long spans which often are necessary to obtain electrical clearances, and show economy in supporting structures.

**SWITCHBOARD CONSTRUCTION.**—Aluminum may be used to advantage in bus bar construction, both on switchboards and for general transmission of power. Aluminum bus bars are rolled and are available in the usual rectangular cross-sections, as well as in channels and certain other structural shapes, which offer definite advantages in strength and current-carrying capacity. The current rating of aluminum bus bars may be conveniently taken as 80% of the accepted values for copper of equal cross-section and similar shape.

**ELECTRICAL MACHINERY.**—Aluminum is used for the rotor windings of squirrel-cage induction motors and also for field windings in certain types of motors and high-speed turbo-generators. The remarkable property of insulating aluminum wire by means of an electrolytically-applied oxide film is of service in constructing windings for electrical machinery where space is limited, or where a heat-resistant insulation is necessary.

## 10. STRUCTURAL USES OF ALUMINUM

Aluminum alloys are used in many structural fields where savings in dead weight, or freedom from rust stains are particularly desirable. They are widely used in aircraft, and for the main structural parts of truck bodies, railroad cars, storage tanks, dragline crane booms, traveling shop cranes, bridges, and special types of buildings. They may be sheared, sawed, punched, and otherwise handled in the routine fabricating operations without difficulty, and with the same tools that ordinarily are used in structural steel shops. Certain alloys are more important than others. These are as follows:

**3S Alloy** is used where welding is necessary, or in structural work where strength is not of primary importance. The hardest temper suitable to the necessary shop work generally is used. Typical applications are tank cars, storage containers, car and bus body plates, corrugated roofing, etc.

**4S Alloy** is used for applications similar to those of 3S alloy. For a given temper, however, 4S is considerably stronger than 3S. In the harder tempers, yield strength is comparable to that of the heat-treated alloys, but the ultimate strength is lower and the amount of forming which can be done is limited.

**17S Alloy** ages naturally at room temperatures following heat treatment, and hence does not have a stable as-quenched condition. Its tensile and yield strengths compare with those of ordinary structural steel, and the alloy is used for important strength members. When cold worked after heat treatment, the alloy, known as 17S–RT, has higher properties, as indicated in Table 8. 17S–RT tubing and sheet are widely used in aircraft construction.

**51S Alloy** in the as-quenched, or W, condition is adapted to severe forming operations. It can be artificially aged to 51S–T after forming, thereby gaining additional strength. 51S–T has the same yield strength as 17S–T, but its other mechanical properties are somewhat lower. See Table 8. 51S–W is used in body framing of railway cars and buses, and in various welded constructions where the strength of 3S is insufficient.

**52S Alloy** has mechanical properties comparable with those of 4S, and forming characteristics which compare with those of 3S. Rolled or extruded shapes, however, cannot be cold worked sufficiently to obtain the properties of the harder tempers. The properties of shapes usually are intermediate between those of the annealed and $^1/_4$ H tempers. Largely because of this, the structural uses of 52S generally are confined to the forms of sheet and plate.

**53S Alloy** is quite similar to 51S. Its mechanical properties are slightly lower and its ductility somewhat greater. It has better corrosion resistance, especially when compared with 51S–T. Its uses are similar to those of 51S alloy. Additional uses are window sash, railings, store-fronts, and various architectural trim.

**Casting Alloys.**—No. 12 alloy can be used structurally to about the same extent as cast iron. When a tight, leak-proof casting is needed, No. 43 alloy is recommended.

Alloys Nos. 195–T6, 220–T4, and 356–T6 are heat treated to obtain the maximum mechanical properties. They are used to replace malleable iron castings and, in some cases, steel castings. The foundry should be consulted in the selection of the alloy best suited to the conditions under consideration.

# NICKEL AND ITS NON-FERROUS ALLOYS

By Robert Worthington

## 1. PROPERTIES OF NICKEL

**GENERAL PROPERTIES.**—Nickel is a white, malleable, ductile, non-corrodible metal, capable of being rolled into thin sheet or drawn into fine wire. To its alloys it imparts strength, combined with ductility, a white color and resistance to oxidation and corrosion. The commercial grades are shown in Table 1. General properties are given in Table 2, and mechanical properties in Table 3.

The principal non-ferrous alloys of nickel are as follows:

**Nickel-copper.**—Nickel content up to 70%; used for corrosion resistance, electrical resistance and where strength, workability and appearance are desired.

**Nickel-copper-zinc.**—Nickel content, 5 to 30%; used for corrosion resistance and where appearance and strength are desired.

### Table 1.—Commercial Grades of Nickel Produced in the United States and Canada

| Grades | Typical Composition | | | | | | | Uses |
|---|---|---|---|---|---|---|---|---|
| | Ni + Co | Fe | Cu | C | Si | Mn | S | |
| Malleable | 99.00+ | 0.30 | 0.25 | 0.10 | 0.10 | 0.25 | 0.010 | Rolling, forging, drawing. |
| Malleable, 5% manganese | 94.00–95.50 | 0.40 | 0.25 | 0.15 | 0.10 | 4.25–5.25 | 0.010 | Spark-plug wire, high temperature applications, etc. |
| Malleable, 2% manganese | 97.00–98.00 | 0.40 | 0.25 | 0.15 | 0.10 | 1.75–2.25 | 0.010 | Electrical resistance wire; spark-plug wire. |
| Anodes; rolled and cast | 99.00+ | ...... | ...... | ...... | ...... | ...... | ...... | Electroplating. |
| Electrolytic, cathodes 27 by 36. in. and smaller cuttings therefrom | 99.95 | 0.01–0.04 | 0.01–0.03 | Trace | Trace | ...... | Trace | Highest-grade material for alloying in steel and non-ferrous metals in electric, open-hearth, or crucible furnaces. |
| Ingot (10, 25, 50 lb.) made by remelting electrolytic cathodes | 99.55 | 0.15 | 0.15 | 0.06 | 0.08 | ...... | 0.010 | For alloying of ferrous metals, particularly where this form is more adapted to the process involved. |
| Shot, made by remelting electrolytic cathodes | 99.55 | 0.15 | 0.15 | 0.06 | 0.08 | ...... | 0.010 | Principally used for crucible charges in ferrous and non-ferrous alloys involving small amounts of nickel. |
| "F" shot and ingot (5 lb.) low melting point | 92.00 | 2.00 | 0.25 | 0.25 | 5.00–6.00 | ...... | 0.05 | For cupola and ladle additions of nickel to gray iron. |

### Table 2.—Properties of Nickel

| | | | |
|---|---|---|---|
| Specific gravity | 8.85 | Pouring temperature, deg. F. | 2895–3000 |
| Density, lb. per cu. in. | 0.319 | Forging temperature, deg. F. | 1600–2300 |
| Melting point, deg. F. | 2624 | Annealing temp., open anneal, deg. F. | 1650–1740 |
| Specific heat, mean, 68°–2624° F. | 0.134 | " " box " deg. F. | 1400 |
| Coefficient of expansion per deg. F. | | Pattern shrinkage, in. per ft. | 1/4 |
| 77°–212° F. | 0.000 00733 | Electrical resistivity at 20° C., ohms per mil.-ft. | 64 |
| 77°–572° F. | 0.000 00800 | | |
| 77°–1112° F. | 0.000 00861 | Temperature coefficient of resistivity at 20–100° C. | 0.00537 |
| Thermal conductivity, mean, 32–212° F., B.t.u. per sq. ft. per hr. per deg. F. per in. thickness | 406.4 | Young's modulus | 30,000,000 |
| | | Modulus in torsion | 10,000,000 |

### Table 3.—Mechanical Properties of Nickel

| | Tensile Strength, 1000 lb. per sq. in. | Yield Point, 1000 lb. per sq. in. | Elastic Limit, 1000 lb. per sq. in. | Elongation, per cent in 2 in. | Reduction in area, per cent | Brinell Hardness | | Shore Scleroscope Hardness | Rockwell B Hardness | Izod Impact, ft.-lb. |
|---|---|---|---|---|---|---|---|---|---|---|
| | | | | | | 500 kg. | 3000 kg. | | | |

* Endurance limit 26,000–30,000 lb. per sq. in.

**Nickel-chromium.**—Nickel content, over 80%; used for electrical and oxidation resistance.

**MALLEABLE NICKEL** is ductile and can be fabricated by drawing, stamping, spinning and machining. Cold working improves its strength, as does forging in the lower temperature ranges where the stresses of working are not relieved, *i.e.*, in the temperature range of 1000–1200° F. The strength of malleable nickel, as regularly supplied, ranges from 60,000–115,000 lb. per sq. in., although the strength of spring wire will be as high as 150,000 lb. per sq. in. with correspondingly low ductility. Malleable nickel is made into plate, sheet, strip, bar, rod, wire, tubing, forgings and castings.

**Uses.**—Malleable nickel is used in the construction of caustic evaporators and food processing and chemical equipment, because of its high corrosion resistance. It is used in automotive spark-plug wire and furnace equipment because of its resistance to high-

temperature oxidation. It is used in coinage because of its toughness and appearance. It also is used in vacuum tubes, because of its high melting point, purity and ease of fabrication.

**Nickel-clad Steel** is used for tanks, tank cars, and heavy plate construction. It consists of mild steel with 10 to 20% nickel bonded to one side of it. The bond is permanent under pressure, vacuum, temperature change and deformation in forming.

## 2. ALLOYS OF NICKEL AND COPPER

Copper alloys with nickel in all proportions to form solid solutions. Strength and toughness increase with increase of nickel content up to 70–80% Ni. The alloys of high copper content are relatively soft, highly ductile and easily fabricated. Alloys are pink in color up to about 25% Ni. Above 25% Ni, the alloys are white. Nickel-copper alloys are malleable both hot and cold. Table 4 gives typical properties of nickel-copper alloys.

Cold working increases the strength and hardness of nickel-copper alloys, the effect being greater on alloys of high Ni content than on low Ni alloys. Thus, the tensile strength of spring temper Monel metal is about 150,000 lb. per sq. in., and that of 80–20 cupro-nickel is about 85,000 lb. per sq. in. Typical values of the tensile properties of nickel-copper alloys are given in Table 5.

**USES.**—Nickel-copper alloys are made for a wide variety of uses under different trade names. The following are the more important of these alloys, together with their trade names: 65–75% Ni, Monel metal, Luceto; general purpose alloys. 40–45% Ni, Constantan, Advance, Copel, Excelsior, Cupron, Ferry; resistance wire, pyrometer wire. 30% Ni, Everbrite, Davis Metal; valve castings, etc. 20–30% Ni, Cupro-nickel, Ambrac (5% Zn), Adnic; condenser tubes. 25% Ni; coinage. 20% Ni, Cupro-nickel; turbine blading. 15–20% Ni, Cupro-nickel; bullet jackets. 2–4% Ni; heat exchanger tubes.

### Monel Metal*

The composition of Monel metal is as follows: Ni, 65–70%; Cu, 26–30%; Fe, up to 3%; Mn, up to 1.5%; Si, up to 0.25%; C, up to 0.25%. In spring wire, the Si content may range up to 1.25%, or Mn may be as high as 2.50%. High-strength castings may have a Cu content up to 34% and Si up to 4%. Monel metal is white, malleable and ductile, both hot and cold, and corrosion-resistant. Its appearance, physical and mechanical properties resemble closely those of malleable nickel. It is fabricated into cold-drawn, hot-rolled and forged rod, bars and shapes, cold-drawn wire, hot-rolled plate, cold-rolled sheet and strip, seamless tubing, and castings. Table 6 gives typical properties of Monel metal. Table 7 and 8 show the tensile properties at normal and elevated temperatures.

**"K" MONEL METAL** is a special grade of Monel metal, containing about 3.75% aluminum, which is hardened and made stronger both by heat treatment and cold working. Quenching in water from 1400–1500° F. softens it. Slow furnace cooling from 1000–1100° F., with or without previous cold working, hardens it. See Table 9 for properties.

---

* Trademark of International Nickel Co.

USES.—Monel metal is used for interior architectural decoration, trim on household appliances and sheet metal work in kitchens, restaurants, etc., and other places where appearance is of importance. Its high corrosion resistance makes it useful in the handling of acids, alkalis, salt solutions, waters, food products, organic substances and atmospheres at normal and elevated temperatures. It also is used in the construction of pickling equipment, tanks, pumps, valves and agitators used in connection with acids, alkalis, brines and food products. Its strength and toughness causes it to find application to

turbine blading, valves, and other steam handling equipment, marine propeller shafting, springs, bolts on railway signal and electrical systems.

**WORKING QUALITIES OF MONEL METAL.—Hot-working.**—Monel metal may be hot worked in the temperature range 1900–2100° F. With care, the temperature can be extended to 2150° F., but Monel metal loses all malleability at about 2200° F. Hot forging should not be attempted between 1200–1600° F., and only under special conditions between 1600–1900° F. Sulphur-free fuel should be used in the heating furnaces, and a definitely reducing atmosphere is desirable.

**Cold-working** operations, as cupping, drawing, swaging, die-forging, power-hammering, bending and forming, are similar to those performed on mild steel, except that more power is required. Annealing may be either by box or open annealing methods. Sulphur-bearing atmospheres must be avoided, and a reducing atmosphere is desirable.

**Machining.**—Cutting tools for Monel metal should be ground to a 15-deg. to 20-deg. back rake. They should be of high-speed steel. For thread chasing, self-opening die-heads are necessary. For machining operations, sulphur base oil, cut with a paraffin base oil, is better than straight paraffin base oil.

**Welding** may be performed by the various electric and gas methods. A special deoxidizing flux gives the best results in arc welding. In gas welding, the flame must be close to neutral, and on the reducing side. The work must be performed rapidly without rewelding, using fused boric acid as a flux.

**Soldering** may be done with soft solders, either high or low in tin. Lead fillets are used for special purposes. For strong joints, subject to corrosive substances, brazing and silver solders are used.

**Pickling.**—In commercial pickling, the oxide first is reduced by heating and cooling in a reducing atmosphere. The metal then is submerged in a solution of 6 lb. sodium nitrate, 3 lb. sodium chloride, 1 gal. concentrated sulphuric acid per 40 gal. of water, held at 180–200° F. If the reducing treatment cannot be used, the metal is dipped in a hot, moderately strong solution of hydrochloric acid and scrubbed with abrasive.

### Other Nickel-Copper Alloys

**Nickel 40–45 Percent.**—These alloys have a low temperature coefficient of electrical resistance combined with relatively high resistivity (see Table 14). They are used for rheostats and other resistances operating at black heat, and also for low temperature heaters. A high thermoelectric force is developed between these alloys and either iron, copper or nickel-chromium, which permits the use of these combinations in thermocouples for pyrometric work.

**Nickel 20–30 Percent.**—Cupro-nickel tubing made of copper-nickel alloys of 20–30% Ni, either with or without zinc, is used for the more severe air impingement conditions of marine and stationary condensers handling sea water, or corrosive inland waters, at high velocity.

**Nickel 15–20 Percent,** known as high ductility cupro-nickel, may be subjected to excessive cold work in drawing and forming, without intermediate anneal. These alloys are used as bullet envelopes and for deep drawing.

## 3. ALLOYS OF COPPER, NICKEL, AND ZINC

Alloys of copper, nickel and zinc, known commercially as Nickel Silver or German Silver usually are designated by the Nickel content, *e.g.*, 18% nickel-silver. Nickel-silver ranges from about 10–25% Ni and 3–40% Zn. These ranges cover the common casting and cold-working alloys. Alloys containing up to 10% nickel, with high zinc, regularly are extruded. Some alloys of 10–15% Ni are extruded in the simpler shapes. Alloys containing up to 10% Zn can be hot worked, but not hot extruded. Table 11 shows the composition of wrought and cast nickel-silver compositions in commercial use. Table 10 gives the physical properties and Tables 12 and 13 the mechanical properties of nickel-silver.

**Table 10.—Physical Properties of Nickel-silver Alloys**

| Composition | | Specific Gravity | Lb. per cu. in. | Melting Point, deg. F. | Thermal Expansion per deg. F. | Composition | | Electrical Resistivity Ohms per mil.-ft. |
|---|---|---|---|---|---|---|---|---|
| Ni | Zn | | | | | Ni | Zn | |
| 30 | 23 | 8.74 | 0.316 | ........ | .......... | 28.6 | 9.8 | 250 |
| 20 | 5 | 8.84 | .319 | 2100 | 0.000 009 06 | 17.4 | 26.7 | 166 |
| 18 | 27 | 8.68 | .314 | 1920 | .......... | 19.8 | 18.5 | 178 |
| 18 | 17 | 8.75 | .316 | ........ | .......... | 15.75 | 29.7 | 167 |
| ...... | ...... | ........ | ...... | ........ | .......... | 7.80 | 31.8 | 111 |

Cold working increases the strength of nickel-silver alloys. For example, spring temper sheet and strip, of 18% Ni, 27% Zn, has a tensile strength of about 120,000 lb. per sq. in. Spring temper wire of the same composition has a tensile strength of about 140,000 lb. per sq. in.

## 4. ALLOYS OF NICKEL AND CHROMIUM. RESISTANCE ALLOYS

Alloys of nickel with 20% or less of chromium have both high electrical resistivity and good resistance to temperatures up to 2150° F. This makes them highly suitable for use as elements in electrical resistance heating devices. Data on these alloys are given in Table 14. Nickel-chromium alloys, particularly those containing iron, are extensively used in high temperature service other than electrical resistance service, and in handling corrosive substances. For data concerning the Ni-Cr-Fe heat-resisting alloys containing upwards of 25% Fe, and the Ni-Cr-Fe austenitic stainless steels containing 70–74% Fe, see pp. 3–19 to 3–24.

# MAGNESIUM AND ITS ALLOYS

By John A. Gann

## 1. PROPERTIES

**PROPERTIES.**—Magnesium is a silver-white metal, produced commercially by the electrolysis of molten anhydrous magnesium chloride, with an average magnesium content of 99.94%. A special grade with a magnesium content of 99.99% may be made by sublimation of commercial magnesium. The properties of magnesium are as follows: Atomic weight, 24.32; density, lb. per cu. in., at 68° F., 0.0629, at melting point (solid), 0.0592, at melting point (liquid), 0.0567; boiling point, 2006.6° F.; mean coefficient of thermal expansion, 68° to 572° F., 0.0000157; 68° to 932° F., 0.0000166 per deg. F.; freezing point, 1204° F.; thermal conductivity, 1102 B.t.u. per hr. per sq. ft. per deg. F. per 1 in. thickness; heat of vaporization, 2340–2700 B.t.u. per lb.; latent heat of fusion, 126 B.t.u. per lb.; mean specific heat, 32 to 212° F., 0.249. The mechanical properties are: tensile strength, 27,000 lb. per sq. in.; yield strength (set = 0.2%), 10,000 lb. per sq. in.; elongation in 2 in., 15%; Brinell hardness, 10-mm. ball, 500-kg. load, 37; modulus of elasticity, 6,250,000. The electrical resistivity at 20° C. is 4.4611 microhms per cu. cm., or 26.83 ohms per mil-ft. The electrical conductivity at 20° C. in percent of International Annealed Copper Standard is, mass, 197.7, volume, 38.6; the temperature coefficient of resistivity at 20° C. is 0.0040. The crystal form of magnesium is close packed hexagonal. Its reflectivity for white light is 73%.

**USES.**—The chemical uses of magnesium are based on its chemical reactivity in a finely divided form or at high temperature, and include pyrotechnics, flares, desulphurization of nickel and nickel alloys. Used as an alloying metal, it improves the physical properties of aluminum and zinc die-casting alloys. Magnesium is the basis of the lightest structural alloys, both in the form of castings and shapes. See Magnesium Alloys below.

## 2. MAGNESIUM ALLOYS

**PROPERTIES.**—Commercial alloys have a magnesium content of from 88–99%. The composition, trade names and uses of such alloys are given in Table 1. Lightness is the principal characteristic of these alloys. Taking the weight of magnesium alloys as 1 the relative weights of other alloys are: aluminum, 1.5; cast iron and steel, 4; brass and bronze, 5. On an equal weight basis, the strength of magnesium alloys is equal to or superior to that of most metals. Strength decreases with increase in temperature, and in general, magnesium alloys are not suited for use at temperatures over 400° F. The characteristics of magnesium alloys are high tensile strength, toughness, and good fatigue endurance. Table 2 shows typical physical and mechanical properties of magnesium alloys and Table 3 compares mechanical properties of various structural alloys.

**CORROSION.**—Magnesium alloys are stable under ordinary exposure conditions, the surface gradually darkening with no decrease in strength. In heavy industrial areas, or in humid atmospheres along the seacoast, surface roughening may occur, and some protection may be desirable. Aqueous salt and acid solutions corrode magnesium alloys, with the exception of pure chromic acid, pure concentrated hydrofluoric acid, and alkali metal fluorides, chromates, and bichromates. The alloys are resistant to attack by most alkalies and many organic chemicals, including hydrocarbons, phenols, and oils.

§ Tentative specifications for magnesium-base alloy bars, rods, and shapes.

**Protection.**—Paints, varnishes, lacquers and enamels can be applied to magnesium alloys. Synthetic resin varnishes and enamels are the best coatings for protection and high-grade finish. Baked finishes have excellent adhesion, hardness and toughness of film and can be applied rapidly.

Before painting, the metal should be cleaned and then chrome-pickled by a short-time dip in a bath of 1.5 lb. $Na_2Cr_2O_7$ and 1.5 pt. of concentrated nitric acid per gallon of solution. A thorough wash and rapid drying should follow the dip. This treatment produces a dull, iridescent bronze finish, combining a mechanical "tooth" and a chemically inhibitive film which improves adhesion and the protective value of the paint coating.

## 3. FABRICATION AND USE OF MAGNESIUM ALLOYS

Magnesium alloys are available as castings and wrought forms. Sheet is rolled in sizes up to 20 ft. long and 48 in. wide. Structural shapes comprise round, square and hexagonal bars, angles, I-beams, channels and special sections. They are produced by extrusion.

**CASTINGS** range in weight from a few ounces up to 700 lb. Die-castings can be made up to 3 lb., with a projected area up to 100 sq. in. Castings normally are made in green sand. Small amounts of fluoride, sulphur, boric acid or other materials should be added to the sand to inhibit the action of water vapor on the hot metal. Castings also may be made in dry sand. Pattern equipment used for aluminum will be satisfactory for magnesium alloys.

**Shrinkage Allowance** for moderate size castings, or with unrestrained shrinkage is $^3/_{16}$ in. per ft. For large castings it is $^5/_{32}$ in. per ft.

The properties of as-cast magnesium alloys are satisfactory for many industrial applications. Heat treatment, however, will greatly improve the properties of most of the alloys, and is recommended for severe service conditions.

**HOT AND COLD WORKING.**—Magnesium alloys can be extruded, rolled, forged and formed at temperatures of 400–800° F. Working speeds should be moderate and bend radii generous. The alloys work-harden at room temperatures more rapidly than other metals, and cold working operations should be limited to simple steps with small changes in shape or cross-section.

**JOINING.**—**Riveting.**—Magnesium alloy parts should be riveted with aluminum alloy rivets containing no nickel or copper. Rivet holes should be $^1/_{64}$ to $^1/_{32}$ in. larger than rivet diameter. Bearing strength of magnesium alloy sheet is approximately 50% greater than its tensile strength. Dissimilar metals in contact with magnesium alloys should be separated by bitumastic paint or reinforced red lead to inhibit galvanic corrosion.

**Welding** may be performed by the oxyacetylene, electric spot, and seam welding processes. The technique is similar to that used with aluminum. Oxyacetylene welds should be made with a filler rod, of the same approximate composition as the base metal, and a flux. The welds will be as strong as as-cast metal. Complete removal of flux after welding by washing in hot water, followed by a chrome pickle, is necessary to avoid corrosion.

Electric spot and seam welds are made on machines with water-cooled electrodes. Welds on $^1/_8$ in.-sheet have a strength of approximately 1800 lb. per spot, or 20,000 lb. per lineal foot of seam.

**MACHINING.**—Magnesium alloys may be machined at higher speeds and with greater depth of cut than any other common metal. Sharpness and proper clearance of cutting tools are essential. Tools for turning, shaping, planing and parting should have a minimum side clearance of 6 deg., with little or no top rake, and an included tool angle of 75 deg. Spiral-type milling and reaming tools are recommended. They should be ground without land and have about 6 deg. relief behind the cutting edge. Ordinary twist drills ground to standard shapes are satisfactory. Threads may be cut in the lathe or by standard four-fluted taps. The alloys finish smoothly and with no tendency to tear or drag. Cutting compounds are recommended for screw machine work and other high-speed operations.

**USES.**—Magnesium alloys are used for airplane parts, including crank-cases, starting equipment, instrument housings, and landing and tail wheels. Sheet, plate and structural shapes are used to decrease the dead-load weight of trucks and trailers. The alloys also are used in portable tools and high-speed automotive equipment to decrease weight and increase operating efficiency.

# TUNGSTEN AND MOLYBDENUM

By Zay Jeffries

## 1. TUNGSTEN

Tungsten is a metallic element with peculiar properties that render it highly important in industry. Tungsten ingots for working are pressed from dry powder and heated to a temperature near the melting point to consolidate the metal. The resulting ingots are brittle when cold, but somewhat malleable when hot.

In swaging an ingot from about $^1/_4$ in. square, the work all being done at high temperature, the rod is brittle cold and malleable hot until the swaged rod is about 50 mils diameter. At a size near 50 mils diameter, above or below as the working temperature is low or high respectively, the swaged rod becomes ductile when cold.

**Table 1.—Tensile Strength of Tungsten**

| Kind of Material | Diameter, mils | Tensile Strength, lb. per sq. in. | Kind of Material | Diameter, mils | Tensile Strength, lb. per sq. in. |
|---|---|---|---|---|---|
| Sintered tungsten ingot | 200 × 250 | 18,000 | Drawn wire........ | 5.78 | 366,000 |
| Swaged rod.......... | 216 | 50,000 | " " ........ | 5.50 | 378,000 |
| " " .......... | 125 | 107,000 | " " ........ | 3.96 | 483,000 |
| " " .......... | 80 | 176,000 | " " ........ | 1.14 | 590,000 |
| " " .......... | 26 | 215,000 | " " ........ | 1.00 | 650,000 |
| Drawn wire.......... | 18 | 264,000 | " " ........ | 0.50 | 700,000 |
| " " .......... | 7.23 | 340,000 | | | |

**PHYSICAL AND MECHANICAL PROPERTIES.**—The properties of tungsten are: atomic weight, 184.0; density, from 0.672 to 0.690 lb. per cu. in.; melting point, 6120° F. (highest of all metals, and, among the elements, exceeded only by carbon); coefficient of linear expansion, 0.000 002 467 per deg. F. at 70° F. (Worthing); electrical resistivity at 0 deg. C., 0.000 004 91 ohm-cm. for pure single crystal wire, 0.000 005 05 for ordinary polycrystalline wire; at 20 deg. C., 0.000 005 50. Very fine wire as drawn may have a value as high as 0.000 008, which is reduced to about 0.000 006, or somewhat less, by heating to a high temperature. The average temperature coefficient of resistivity between 0 and 100 deg. C. is about 0.0047 per deg. C. Resistance at 2100 deg. C. is about 12 times, and at 2400 deg. C. about 15 times the resistance at room temperature. Modulus of elasticity is about 57,000,000. Poisson's ratio is 0.17, independent of temperature. The thermal conductivity is 812 B.t.u. per sq. ft. per hr. per deg. F. per 1 in. thickness at 2632° F., 1152 B.t.u. at 32° F., 1610 B.t.u. at −310° F., and 2380 B.t.u. at −422° F. It is weakly paramagnetic. Tungsten crystallizes with a body-centered cubic space lattice, the length of the side of the unit cube being 3.155 Angstrom units,* and the nearest approach of atom centers, 2.732 Angstrom units. Table 1 shows the improvement in tensile strength of tungsten by working.

Drawn tungsten can be treated to a higher temperature than any other metal without removing the effects of working (strain hardening). A 25-mil drawn wire had a tensile strength of 101,000 lb. per sq. in. at 1635° F., a value not equaled by any other metal.

Drawn tungsten wire has some peculiar properties. When ductilized by the swaging and drawing process, it is typically ductile. That is, it can be drawn further cold, but it is not typically malleable; it splits into many fibers when hammered on an anvil. When ordinary drawn metals are heated so as to cause the strain-hardened grains to recrystallize, the ductility, largely lost because of the drawing, is restored. Ductile tungsten so treated becomes brittle at ordinary temperature, and to make it again ductile it must be further worked hot, but below the recrystallization temperature.

**CORROSION.**—Powdered tungsten is black when finely divided and gray when coarse. In air, at ordinary temperatures, the coherent and dense metal slowly oxidizes on the surface until inhibited by a thin film of oxide. Tungsten is dissolved by fused alkali nitrates and slowly attacked by hot *aqua regia* or strong hydrogen peroxide. It is scarcely attacked by hydrochloric, nitric or sulphuric acids, because of the formation of a protective film, or tungstic acid. It is rapidly dissolved by hydrofluoric acid containing nitric acid, giving a clear solution. When heated above a red heat, it oxidizes fairly rapidly. When exposed at high temperatures to carbon monoxide or hydrocarbon gases, two tungsten carbides are formed (reported to be WC and $W_2C$).

**USES.**—Drawn tungsten wire is used for the pressed filaments of incandescent lamps. Tungsten also is used for talking machine needles, filaments for radio and rectifier tubes, electric furnace resistors, and lamp filament supports. Wrought tungsten, made in rods up to about $^{3}/_{4}$ in. diameter, and in sheet, is used principally for x-ray targets and contacts for internal-combustion ignition appliances. Most of the tungsten produced is used in alloy-steel, principally high-speed steel, which contains about 18% tungsten, and in magnet steel. Tungsten is added to steel either as tungsten powder, or preferably as ferro-tungsten containing at least 75% tungsten.

**CEMENTED CARBIDES.**—Tungsten is the most important element in the so-called cemented carbides used extensively for cutting tools, wire drawing and other dies, and wearing parts of machinery. The cemented tungsten carbide is made by mixing very fine tungsten powder approximating the composition of WC, with about 3 to 20% by weight of metallic cobalt, according to the hardness and wearing properties desired, and sintering at a temperature far below the melting point of the tungsten carbide. This material is relatively expensive as compared with the common cutting tools, and tools usually are made by copper-brazing a small tip of cemented carbide to a steel shank. Drawing dies usually are made by mounting a small piece of cemented carbide in a steel casing. Other carbides, as tantalum carbide and titanium carbide, have been added to tungsten carbide, principally for enhancing the steel-cutting qualities.

---

* 1 Angstrom unit = $10^{-8}$ centimeter.

## 2. MOLYBDENUM

Molybdenum is a hard, silvery-white metallic element. Wire is made by hot drawing, at least in the early stages of drawing. The ingots are prepared by pressing powdered metal and consolidating below the melting point. These are brittle when cold and must be worked hot. After the hot working has progressed to a certain point, the rod becomes ductile when cold.

**PHYSICAL AND MECHANICAL PROPERTIES.**—Some of the properties of molybdenum are: atomic weight, 96.0; density, 0.3688 lb. per cu. in.; coefficient of linear expansion, 0.000 002 77 per deg. F. at 70° F. (Worthing); electrical resistivity at 0 deg. C., 0.000 005 08 ohm-cm.; at 2000 deg. C., 0.000 006 15; average temperature coefficient of resistivity between 0° and 100° C., 0.0047; thermal conductivity, 992.4 B.t.u. per sq. ft. per hr. per deg. F. per 1 in. thickness. It is weakly paramagnetic. Molybdenum crystallizes with a body-centered cubic space lattice, the length of a side of the unit cube being 3.142 Angstrom units and the nearest approach of atom centers 2.720 Angstrom units. Table 2 gives typical mechanical properties of molybdenum wire, 25 mils diameter, treated in various ways.

Brittle molybdenum can be ductilized like tungsten by working below the recrystallization temperature. Unlike tungsten, drawn wire can be recrystallized with an increase in ductility if the annealing temperature is low, say 1920° F., so as to produce a fine-grained structure. Higher annealing temperatures produce larger grains, causing a diminution in cold ductility.

**CORROSION.**—Dense and coherent molybdenum slowly oxidizes superficially, until action is stopped by air at ordinary temperatures with the formation of a protective film of oxide. At red heat, the oxidation proceeds rapidly with the formation and volatilization of molybdenum trioxide. Molybdenum is attacked or dissolved by nearly all reagents which attack tungsten. It is soluble in nitric acid, sulphuric acid and hydrogen peroxide.

**USES.**—Molybdenum is used mostly as an alloying element in steel. Although it imparts characteristics to steel somewhat similar to those imparted by tungsten, the two metals are not interchangeable, volume for volume. Molybdenum never has been as successful in high-speed steel as tungsten. It is used chiefly in structural steels for automobiles in amounts less than 1%. The wrought metal is used for x-ray targets, the wave length being quite suitable for the study of crystal structure.

**Table 2.—Mechanical Properties of Molybdenum**

| Description | Tensile Strength, lb. per sq. in. | Elongation in 2 in., percent | Reduction of Area, percent |
|---|---|---|---|
| Swaged and drawn hot (1000–1300° C.) from 25 to 125 mils | 148,000 | 4.7 | 68 |
| Swaged and drawn hot (black heat–800°) from 25 to 125 mils | 154,000 | 5.7 | 65 |
| Annealed to produce large grains........................ | 42,500 | 3.15 | None |
| Annealed to produce very small grain size............... | 125,000 | 20.0 | 66 |

# DIE-CASTING ALLOYS

**By J. C. Fox**

Die-casting alloys may be classified as: 1. Tin-base alloys; tin, alloyed with copper, antimony and tin. 2. Lead-base alloys; lead, alloyed with antimony or antimony and tin. 3. Zinc-base alloys; zinc, alloyed with aluminum, magnesium and copper. 4. Aluminum-base alloys. 5. The brasses and bronzes; copper alloyed with zinc, tin, lead, aluminum, nickel, manganese, etc. 6. Magnesium-base alloys; magnesium, alloyed with aluminum, manganese and nickel.

General properties and application of typical alloys of each group are described below:

**TIN-BASE ALLOYS.**—The compositions of typical tin-base alloys, used in die-casting, are as follows:

| Alloy No.............. | 1 | 2 | 3 | 4 |
|---|---|---|---|---|
| Copper, percent........ | 4.50 | 6.00 | 7.75 | 3.00 |
| Antimony, “ ........ | 4.50 | 8.00 | 7.75 | 10.50 |
| Lead, “ ........ | ..... | ..... | 1.75 | 25.00 |
| Tin, “ ........ | 90.00 | 86.00 | 82.75 | 61.50 |

Alloy No. 1 is the highest quality "babbitt" mixture corresponding to S.A.E. specifications for No. 10 Babbitt. It is used for main-shaft and connecting-rod bearings in the automotive and aircraft industries. No. 2 fulfils S.A.E. specification No. 11, and is used for bearings and other applications requiring a high-class tin-base alloy. No. 3 is a special automotive bearing composition. No. 4 (S.A.E. Specification No. 12), because of the high lead content, costs less than the others.

**LEAD-BASE ALLOYS.**—The composition of typical lead-base die-casting alloys is as follows:

| Alloy No. | 5 | 6 | 7 | 8 |
|---|---|---|---|---|
| Antimony, percent | 5 | 10 | 17 | 15 |
| Tin, " | .. | .. | .. | 5 |
| Lead, " | 95 | 90 | 83 | 80 |

Lead-base alloys are used where strength, hardness and other mechanical properties are not important, and a cheap non-corrosive metal is required. In chemical industries, lead-base alloys are used to resist the action of strong mineral acids. Because of their opacity to x-rays, these alloys are used in x-ray apparatus.

**ZINC-BASE ALLOYS** in common use conform to A.S.T.M. Designation B86–34T and S.A.E. Standards 921 and 903.* Composition of the alloys is as follows:

| | Cu | Al | Mg | Fe * | Pb * | Cd * | Sn | Zn |
|---|---|---|---|---|---|---|---|---|
| A.S.T.M. alloy XXI<br>S.A.E. alloy 921 | 2.50–3.50 | 3.50–4.30 | 0.02–0.10 | 0.100 | 0.007 | 0.005 | 0.005 | Remainder |
| A.S.T.M. alloy XXIII<br>S.A.E. alloy 903 | 0.10† | 3.50–4.30 | 0.03–0.008 | 0.100 | 0.007 | 0.005 | 0.005 | |

Stability of properties, dimensions and corrosion resistance require that the percentages of lead, tin and cadmium, as given above, be not exceeded. Highest purity metals must be used, *i.e.*, zinc, 99.99%+; electrolytic copper; aluminum, 99%+; magnesium, 99.9%+. Contamination by injurious metals during melting and casting must be avoided. Minimum physical properties, as called for by the A.S.T.M. and S.A.E. standards are as follows:

| | Tensile Strength | Charpy Impact | Elongation in 2 in. |
|---|---|---|---|
| Alloy XXI | 44,000 lb. per sq. in. | 6.0 ft.-lb. | 2% |
| Alloy XXIII | 35,000 " " " | 12.0 " | 3% |

**Table 1.—Physical and Mechanical Properties of Zinc-base Die-casting Alloys**

| Property | Alloy XXI | Alloy XXIII |
|---|---|---|
| Specific gravity | 6.7 | 6.64 |
| Density, lb. per cu. in. | 0.2421 | 0.2399 |
| Melting point, deg. F. | 734 | 728 |
| Specific heat | 0.10 | 0.10 |
| Thermal conductivity, B.t.u. per sq. ft. per hr. per deg. F. per 1 in. thickness | 725.7 | 783.8 |
| Thermal expansion, per deg. F. | 0.000 001 52 | 0.000 001 54 |
| Electrical conductivity at 25° C., microhms-cm. | 144,000 | 155,000 |
| Tensile strength, lb. per sq. in. | 48,000 | 40,000 |
| Elongation in 2 in., percent | 5 | 5 |
| Compressive strength, lb. per sq. in. | 93.000 | 60,000 |
| Shearing strength, lb. per sq. in. | 45,800 | 31,000 |
| Transverse deflection, in. | 0.22 | 0.27 |
| Brinell hardness No. | 83 | 74 |
| Charpy impact strength, ft.-lb. (1/4 × 1/4 in. bar) | 19 | 20 |

Table 1 gives average physical and mechanical properties of alloys XXI and XXIII, as determined from die-cast test bars, made in accordance with the A.S.T.M. specifications. Although alloy XXI has greater tensile strength and hardness than alloy XXIII, the latter, because of its greater dimensional stability and higher impact strength, which remains unchanged even under the severest conditions, usually is favored for applications requiring strict maintenance of properties and dimensions. Pressure die-castings made from these alloys have high strength, high ductility, resistance to impact, good corrosion resistance, and are easily machined. Practically every type of commercial finish may be satisfactorily applied. Zinc-base die-castings are used for automotive parts, household and office appliances, and miscellaneous articles.

**ALUMINUM-BASE ALLOYS.**—See p. 4–37.

---

* These alloys also conform to the "Zamak" series of the New Jersey Zinc Co. (U. S. Patents 1596761, 1779525, 1852441).

† Maximum.

**COPPER-BASE ALLOYS.**—The composition of typical copper-base alloys, cast by a process perfected by Doehler Die Casting Co., in 1931, are as follows:

| | Copper | Zinc | Tin | Silicon |
|---|---|---|---|---|
| Alloy No. 1.... | 57.0–59.0 | 40.0–42.0 | 0.5–1.50 | ......... |
| " No. 2.... | 63.0–66.0 | 32.0–34.0 | ........ | 0.75–1.25 |
| " No. 3.... | 80.0–81.5 | 13.5–15.0 | ........ | 4.0–5.0 |

The mechanical properties are:

| | Tensile Strength | Yield Strength | Elongation in 2 in. | Brinell Hardness |
|---|---|---|---|---|
| Alloy No. 1.. | 55,000–65,000 lb. per sq. in. | 35,000–40,000 lb. per sq. in. | 15–20% | 120–130 |
| " No. 2.. | 65,000–75,000 " " " | 35,000–40,000 " " " | 15–20% | 110–120 |
| " No. 3.. | 85,000–95,000 " " " | 65,000–70,000 " " " | 10–15% | 160–180 |

**MAGNESIUM-BASE ALLOYS** are described on p. 4–55. The A.S.T.M. has issued a specification, Designation B94–34T, for an alloy with a specific gravity of 1.80, as follows: Magnesium, 88.0%; aluminum, 9.0—11.0%; manganese, min., 0.10%; nickel, max., 0.03%; copper, max., 0.05%.

## BEARING METALS

By Christopher H. Bierbaum

**BEARING METALS** are alloys composed of two or more metals in proportions in which they do not enter into a solid solution. They consist of relatively hard and soft microscopic particles or crystals intimately mixed. The function of the hard particles or bearing crystals is to support the load and resist the wear at times when actual metallic contact exists between the bearing surfaces. The softer particles, in a measure, owing to their plasticity, allow the harder particles to adjust themselves to the surface requirements of the journal. The softer particles also wear down lower than the harder particles and thus form slight depressions on the apparently smooth bearing surface. These depressions retain some of the lubricant and thereby effect a residuary lubrication, sufficient to prevent scoring or cutting during metallic contact. The property of a metal to retain lubrication upon a "run-in" bearing surface characterizes it as a bearing metal, and its capacity for doing so largely determines its value as such. A bearing metal, therefore, may be defined as an alloy that is capable of retaining a lubricant upon a bearing surface. Heretofore a run-in bearing surface could be produced only under service conditions, wherein it was necessary that all the disturbed metal on the surface, incident to tooling, should first be worn off; this was tedious and often caused bearing surface inaccuracies before a run-in condition was obtained. Since 1935, however, a high state of perfection of diamond tooling has enabled the production of bearing surfaces that approach insensibly close to those run-in in service.

This effects a twofold economy: it reduces the time for fitting and running-in; and it enormously prolongs the life of bearings. Nevertheless, journal and bearing should mutually polish each other. Bearing and journal therefore should bear some relation to each other, *i.e.*, their hardest particles, for best results, should be of the same order of hardness. These requirements would not be imperative, were the journal to possess infinite hardness and the cylindrical surface be ideally true. A highly accurate, ground and polished journal surface of chromium plate, nitrided nitralloy steel, or hardened tooled steel closely approaches this ideal state. The mating member, nevertheless, should have the microstructure of a bearing metal.

It is essential that, with two surfaces bearing together, one, say the journal, should have the highest possible microscopic homogeneity, and the other a heterogeneity, corresponding to that of a bearing metal.

**BABBITT METALS.**—The alloys in Table 1 are from A.S.T.M., 1933 Standards, Part 1, p. 845. These alloys cover the field very completely and can be recommended for the uses outlined below:

**No. 1** is suited for crank-pin service in steam and internal-combustion engines. It should be well confined in its backing or be used as a thin layer sweated on bronze or steel. It is the least likely to crack and the most plastic of the tin-base alloys.

**No. 2** is suited for substantially the same service as No. 1. It has, however, a higher bearing value, and is less likely to pound out. Like No. 1, it is especially suited for sweating on, owing to its high tin content.

**No. 3** is the hardest babbitt and has the highest bearing value. When allowed to cool and solidify very slowly, it develops the $SnCu_3$ crystal, which is the hardest copper-tin

Table 1.—Composition and Physical Properties * of White Metal Bearing Alloys

| 12 | ...... | ...... | 10.0 | 90.0 | 10.67 | 0.12 | 0.11 | 9.9 | 89.4 | 2800 | 1250 | 2250 | 950 | 12,900 | 5100 | 14.5 | 6.5 | 473 | 498 | 625 |

* The compression test specimens were cylinders $1\frac{1}{2}$ in. long and $\frac{1}{2}$ in. diameter, machined from chill castings 2 in. long and $\frac{3}{4}$ in. diameter. The Brinell tests were made on the bottom face of parallel machined specimens cast in a 2-in. diameter by $\frac{5}{8}$-in. deep steel mold at room temperature.

† Permissible variations in percentages of the desired elements are as follows:

| | | | | |
|---|---|---|---|---|
| Percentage of element specified..... | not over 2 | 2–5 incl. | 5–10 incl. | over 10 |
| Permissible variation, units of percent | 0.25 | 0.50 | 0.75 | 1.0 |

‡ The values for yield point were taken from stress-deformation curves at a deformation of 0.125 percent reduction of gage length.

§ Johnson's apparent elastic limit is taken as the unit stress at the point where the slope of the tangent to the curve is $1\frac{1}{2}$ times its slope at the origin.

‖ The ultimate strength values were taken as the unit load necessary to produce a deformation of 25 percent of the length of the specimen.

¶ These values are the average Brinell number of three impressions on each alloy using a 10-mm. ball and a 500-kg. load applied for 30 sec.

constituent; it, therefore, never should be mated with the softest steels. It is ideal for the highest service requirements when well seated and not subjected to loose pounding.

**No. 4** alloy has excellent bearing value for engine main bearings and general machinery, machine tools, and the like. It will withstand severe punishment and give general satisfaction. It is the most economical tin-base babbitt.

**Nos. 5 and 6** are intermediate alloys, neither tin nor lead base. They are alloys in which the soft matrix contains the tin-lead eutectic, for which reason they become mushy at a relatively low temperature. They are not to be recommended for either service or economy, as compared with Nos. 4 and 7.

**No. 7** is the most economical of the lead-base alloys. Its entire tin content is combined with antimony, giving a high percentage of bearing crystal; for that reason it is very serviceable. It is even suitable for use in many places where the high-tin babbitts are specified.

**Nos. 8, 9, and 10** are all lead-base babbitts belonging to the same general class. Their bearing value decreases with a decrease of tin content. They are serviceable with relatively light loads; with good workmanship they stand high speeds and are suitable for mating with the softer steels.

**Nos. 11 and 12** are antimonial lead alloys and constitute the cheapest grade of babbitt. They should be used for the lightest service only, such as line-shafting and less important bearings; they are suited to mate with the softest steels.

**BRONZE ALLOYS.**—Up to 1936 a vast number of bronze bearing formulas have been evolved, many of them of even doubtful value. The whole range of engineering work, however, can be covered satisfactorily by a comparatively small number of alloys. Those given in Table 2 are an approved list, from which the engineer can select a bearing for any and all requirements encountered in practice. This table is the result of selections and rejections of bearing formulas, during a period of more than 39 years, in an effort to reduce this entire field of alloys to an efficient minimum number.

The phosphorus content of a bronze, be it a trace or an amount not in excess of 0.25%, has no appreciable effect, either on the physical properties or bearing value of the resulting bronze; it is important, however, that deoxidation with phosphorus be specified and a trace of it required in the resulting alloy.

Considerable work and research have been done on casting bearing bronzes centrifugally; so far, however (1937), there is no proved advantage either as to physical properties or bearing value of any centrifugally-cast material. The advantages claimed are entirely due to the chill effect incident to the process, and the question is one of economical production. Chilling, however, can best be controlled in stationary molds.

The importance of high-class workmanship cannot be over-estimated, especially with the harder bearing metals and their harder mating journals. Grinding or lapping is ideal for the production of accurate surfaces, but, owing to the microconstituents of bearing metals, great care should be taken not to leave grinding particles embedded in the softer constituents of the bearing surface.

Two distinct tendencies, during the 16 years preceding 1937, for the improvement of bearing service apply to both bearing alloys and their steel journals: a large number of the more suitable alloys are now being produced, not only as sand cast, but also in a preferred chill cast condition; there is a very general tendency to increase the hardness of journals and shafts. Both conditions have aided materially in improving serviceability of bearings. It therefore has become a more exacting engineering problem to specify the most efficient combinations of bearings and journals. For this reason rather full comments are made on the following list of bronzes and their application. Furthermore, the mere selection of the proper alloy for any particular service does not insure that the bearing will be satisfactory. Many factors, including design, quality of workmanship, accuracy of fitting, clearance, oil grooving, etc., still enter the problem. See pp. 13–03 to 13–58.

**Alloy T–1** is a high-quality, worm gear bronze. As such it may be designated an international standard. It should not be used with very soft or low-carbon steel. In the sand-cast condition it is specified as: S.A.E. 65; A.S.T.M. B22–21 — grade D; A.R.E.A. grade D. Chill casting increases its physical properties. In this condition it has the widest application for motor car, truck, and bus worm gear drives. It also is widely applied in worm gear speed reducers. For best service it should mate with hardened steel, accurately finished and well polished.

**Alloy T–2** is a high-grade gear bronze. Its lead content does not detract from its physical properties, yet is sufficient to permit tooling to be done with greater accuracy than on T–1. It is suitable for elevator worm gears, worm gear speed reducers, spur gears meshing with small steel pinions, where quiet running and the wearing quality of a bronze is essential, feed nuts for working tools, and like service. When sand cast it is specified as S.A.E. 63. Chill casting increases its physical properties, making it an exceptionally high-

* Sand cast. † Chill Cast. ‡ Deoxidized with phosphorus.

grade bearing bronze for very high speeds, as in steam turbine worm wheels. With fair workmanship, at lower speeds it will support relatively heavy loads.

**Alloy T-3**, an intermediate bronze between T–1 and T–7, is a much-used composition for machine tool bearings. It is well adapted for worm gears where the softer steels are used, and also is suitable for steel mill bronze inserts and segmental bearing sections, feed nuts, bushings, and general machinery bearings. Its lead content permits easy and accurate tooling. Chill casting increases the physical properties, especially compressive strength, making it more serviceable for use with heavier loads.

**Alloy T-4** is a nickel-phosphor-bronze. It has the lowest coefficient of thermal expansion of all the copper-tin bearing and phosphor bronzes. It is suitable for heavy punishment when the bearing surface of its mating member is either hardened steel, nitrided nitralloy, or chromium plated, accurately finished and polished, and is also suitable for valve stem guides for internal-combustion engines. The lead content gives it an accurate tooling quality. Chill casting increases its density and refines the grain. It then has wide application for the highest requirements of worm wheel service and speed reducers, both in the largest and smallest sizes. It is favored for small worm wheels in portable tools. For hard bronzes in Diesel engines and like service, if combined with corresponding workmanship and mating material, it is unsurpassed.

**Alloy T–5** is especially adapted to service requiring high compressive strength. It is suitable for low-speed and heavy-pressure journals not exceeding 1500 lb. per sq. in. It is well adapted for thrust bearings, thrust washers, and step bearings, pivot bearings, dies, and trunnions, and is suitable for bascule and lift bridges. With light loads and accurate workmanship it will support an exceedingly high speed. It is specified as: A.S.T.M. B22–21, grade B; and A.R.E.A. grade B.

**Alloy T–6** is adapted to very heavy duty on thrust and pivot bearings for lift and swing bridges and the like, with very high pressures and comparatively low speeds. For this purpose it is second only to Alloy T–11. It should be used only against hardened steel surfaces. Accurately fitted, it will withstand bearing pressures in excess of 1500 lb. per sq. in. It is specified as: Federal Specification Board Q–Q–B–691, composition 10; U. S. Navy 46–B22, grade 4; U. S. Army Ordnance Dept. 57–702, grade 10; A.S.T.M. B22–21, grade A; A.R.E.A. grade A.

**Alloy T–7** is a leaded phosphor-bronze, an old standard for general machine construction, suitable for crosshead and crank-pin bearings and for general machinery, lathes, grinders, etc., for relatively high speeds and journals, not heat-treated. When sand cast, it is specified as: U. S. Navy 46–B22, grade 2; U. S. Army Ordnance Dept. 57–70B, grade 8; S.A.E. 64. Chill casting increases its physical properties materially, causing a finer and more perfect distribution of the lead with a general refinement of grain, making a superior bearing metal for severe punishment.

**Alloy T-8** is a relatively high-lead bronze suitable for brass and copper rolling mill neck bearings and bushings, where the spindles are of soft steel and the speed relatively high. In general, it is adapted for the intermediate or softer grades of steel journals, with intermediate or light pressures and relatively high speeds. It is substantially the famous Penn. R. R. alloy known as Ex. B metal. When sand cast it is specified as: U. S. Navy 46-B22, grade 1; U. S. Army Ordnance Dept. 57-70B, grade 7; S.A.E. 67. Chill casting increases its physical properties materially, owing to the finer distribution of the lead and a general grain refinement, with the result that in the chilled condition this alloy is capable of resisting greater punishment with higher bearing and wearing qualities.

**Alloy T 9** is a relatively high-lead bronze. It is serviceable for bearings where the danger of melting babbitts exists. It fills a field where the harder babbitts are otherwise especially serviceable. On account of its lead content and resulting plasticity, it is serviceable with poor workmanship and a soft steel mating member, in that the copper-tin crystal is hard enough to produce a mutual polishing effect between the bearing and its journal.

**Alloy T 10** is a very high-lead alloy, representing the probable limit of usefulness of high lead content. Its composition and serviceability are substantially those of the old plastic bronzes. It is suitable for poor workmanship, and competes with the intermediate and cheaper grades of babbitt, having the advantage of not melting out when heating.

**Alloy T 11**, Lumen bronze, is a unique hard zinc-base alloy. Its capacity for holding an oil film after it has once been established is unequaled by any other alloy. It is hard and unyielding, and therefore requires care in fitting. It is especially serviceable for use where high compressive strength is required, and has an enviable record for all kinds of bridge bearings, for pivots, thrust collars, bascule trunnion bushings, and bearings in draw, swing, and lift bridges. It is suitable for turntable pivots, cold neck rolling mill table bearings, crane bearings, etc. In electrical and in general machine tool service it has phenomenally long life, and is well suited for fractional-horsepower motors. It must not be subjected to excessive pounding and impact.

**THERMAL EXPANSION OF BEARING BRONZES.**—Table 3 gives the linear coefficients of thermal expansion for the bearing bronzes. It supplies exact data for computing expansions and clearance of bearings at different temperatures. The expansion of these alloys is rather irregular, and therefore, it is necessary that these data be given in each case for several temperature intervals.

# SOLDERS

The two types of solders most generally used are lead-and-tin solders and silver solders. The latter are used in connection with high operating temperatures and for high-strength joints. They also can be used on other metals than copper, including stainless steel. Brazing alloys containing copper and phosphorus cost less than silver solders and are used on copper and copper alloys.

**LEAD-TIN SOLDERS.**—The composition and melting point of lead-tin alloys used as solders, and commercially known as soft solders, are given in A.S.T.M. standard specifications, Designation B32–21. Class A solders are required to be made of new or virgin metal. Class B solders are made from at least one-half virgin metal, the balance being recovered or secondary metals. Only Class A solders should be used on zinc and galvanized iron.

Table 1 shows the composition and melting point of these solders. The solders are completely solid below the temperature given for melting, and completely liquid at temperatures above the liquefaction temperature. Grade 4 is particularly suitable for making wiped joints.

**SILVER SOLDERS** contain a greater or less amount of silver together with varying quantities of copper and zinc, and are used for brazing. Table 2 gives the composition and characteristics of silver solders covered by A.S.T.M. standard specifications, Designa-

* Maximum. † The addition of not over 0.50% cadmium to assist fabrication shall not be considered a harmful impurity.

tion B73–29. Grades 1–3 are suitable for brazing where a freer flowing solder than the ordinary copper-zinc brazing solders is required. Grades 4 and 5 will flow more freely at lower temperatures than grades 1–3. They are used where strong joints are required, and where the temperature necessary to flow grades 1–3 would injure the metal to which the solder is applied. Grades 6–8 are used where a high degree of malleability or ductility is required.

**SOLDERING FLUXES.**—Neutral fluxes, as resin, or resin in alcohol, are non-corrosive. They are used where corrosive action must be avoided, and where washing is impracticable. Their cleaning action is slight and they are not suitable for oxidized surfaces. More active fluxes comprise zinc chloride or ammonium chloride, or both, dissolved in water or mixed with petrolatum paste in various proportions. They are corrosive, and the joints, therefore, should be washed in hot water after soldering. For silver solder and brazing alloys, powdered borax is used as a flux.

# NON-METALLIC MATERIALS

## REFRACTORIES

**Revised by J. Spotts McDowell**

### 1. FIREBRICK

Refractories, generically classed as firebrick, are structural materials used at high temperatures in industrial furnaces. The life of refractories is affected by the high temperatures to which they are subjected, and usually by two or more of the following influences: abrasion; corrosion through chemical action by slags and fluxes; erosion by mechanical action of molten metal or slag, or by dust-laden gases moving at high velocity; spalling of various types; the effect of various gases. The principal types of refractories are fireclay, high-alumina, silica, magnesite and chrome brick. Other types, in the special refractories class, are less extensively used. "Firebrick" when used alone is generally understood to mean fireclay brick. A glossary of the terms relating to refractories is given in Modern Refractory Practice, published by Harbison-Walker Refractories Co., Pittsburgh, Pa.

**REFRACTORINESS OF FIREBRICK (ALL TYPES).**—The terms fusion point, softening point and melting point are indefinite when applied to ceramic materials, which soften over a wide temperature range. No definite temperature marks the transition from the distinctly solid to the distinctly liquid state. Instead, the Pyrometric Cone Equivalent (P.C.E.) is generally used. It is an index of the heat-resisting qualities, or refractoriness of firebrick and other ceramic bodies.

**PYROMETRIC CONE EQUIVALENT** (P.C.E.) is defined, in the case of refractories, as the number of that standard cone whose tip would touch the supporting plaque simultaneously with a cone of the material being investigated, when tested in accordance with the standard method of test for softening point of fireclay brick (A.S.T.M. Designation C24–35). The determination of the P.C.E. (A.S.T.M. designation C24–35) consists in testing cones made of the ceramic material by comparing them with standard pyrometric cones, all heated together in the same furnace. It is made as follows:

1. A sample of the material to be tested is pulverized. The standard grind adopted by the A.S.T.M. is 60 mesh. (U. S. Std. Sieve Series.) 2. From this are molded test cones of similar size and shape as the standard pyrometric cones. 3. A test cone is placed in a suitable furnace with a series of standard cones, and heated at a definite rate until it softens and bends sufficiently for its tip to touch the base. At this temperature, one standard cone usually will have softened to approximately the same extent as the test cone. The number of this standard cone is the Pyrometric Cone Equivalent of the material being tested. Fusion points of standard pyrometric cones are given in Table 1.

**Table 1.—Softening Point of Standard Pyrometric Cones Used in Connection with Refractories***

*Proc.*, A.S.T.M., Vol. xxxiv, Part I, 1934

* Fairchild and Peters, Characteristics of Pyrometric Cones, *Journal* Am. Ceramic Soc., vol. ix, No. 11, p. 701, Nov., 1926. These temperatures, which were determined for a heating rate of 150 deg. C. per hr. for cones 15 to 20, and of 100 deg. C. per hr. for cones 23 to 38, other conditions being the same as specified, apply satisfactorily for all the conditions of this test method, but do not apply to conditions of the commercial firing and use of refractory materials.

**FIRECLAY BRICK.**—The most widely used refractory brick are those made from flint fireclays and plastic fireclays, the essential ingredients of which are hydrous alumina silicates of the general type formula $Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$. A member of this group is kaolinite, a crystalline mineral of comparatively rare occurrence. Formerly, all clays were thought to contain it as their clay base, but the term is now restricted to the native mineral. It occurs in Colorado, Wales, and a few other localities. See The Kaolin Minerals, C. S. Ross and P. F. Kerr, Professional Paper 165–E, U. S. Geological Survey, 1931.

| Alabama Clays | 61.1 | 32.5 | 3.8 | .5 | .4 | 1.8 |

The manufacture of fireclay brick consists in blending the raw materials, flint clay, plastic clay, and calcined clay or grog, either by grinding together in a wet pan, or by grinding together or separately in a dry pan, then mixing and tempering with the addition of water. The brick are molded by hand or mechanically, dried, either on hot floors or in dryers, and fired in periodic down-draft kilns or in continuous tunnel kilns. Table 5 gives pyrometric cone equivalents.

**HIGH-ALUMINA BRICK.**—In many parts of furnaces where the requirements are severe, high-alumina brick may be used to decided advantage. The equilibrium diagram (Fig. 1) of the alumina-silica system is of interest in considering alumina refractories.

High-alumina raw materials include bauxite, diaspore, cyanite, andalusite, sillimanite, and crystalline alumina or corundum. In manufacturing high-alumina brick, *i.e.*, brick containing 50% or more of alumina, these materials are used individually, collectively, or blended with flint and plastic clays according to the properties and percentage of alumina desired in the finished product. High-alumina brick are manufactured by methods similar to those used in manufacturing fireclay brick.

**Table 5.—Pyrometric Cone Equivalents (P.C.E.) for Various Types of Refractory Brick**

| Type | P.C.E. | Temperature Deg. F. | Temperature Deg. C. |
|---|---|---|---|
| Fireclay | | | |

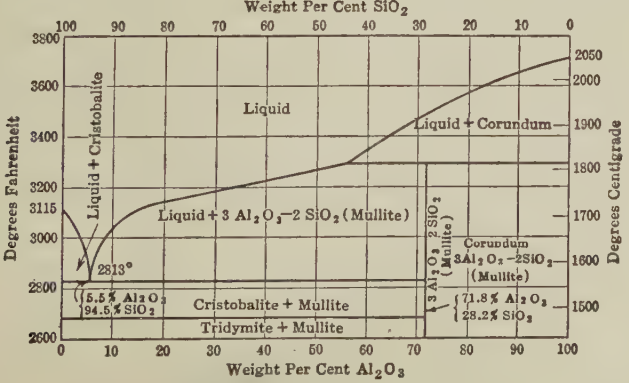

FIG. 1. Equilibrium Diagram of Alumina-silica System

**SILICA BRICK.**—(Abstracted from A Study of the Silica Refractories, J. Spotts McDowell, *Trans.* A.I.M. & M.E., lvii, p. 3, 1917.) The facts and data presented by the author have been subsequently confirmed by other investigators. Table 8 gives typical analyses of quartzites or ganisters from which silica brick are made.

**Table 8.—Typical Analyses of Quartzite**

| | $SiO_2$ | $Al_2O_3$ | $Fe_2O_3$ | CaO | MgO | Alkalies |
|---|---|---|---|---|---|---|
| Medina quartzite (Penna.) | 97.80 | 0.90 | 0.85 | 0.10 | 0.15 | 0.40 |
| Baraboo quartzite (Wisconsin) | 97.15 | 1.00 | 1.05 | 0.10 | 0.25 | 0.10 |
| Alabama quartzite | 97.70 | 0.96 | 0.80 | 0.05 | 0.30 | 0.31 |
| Colorado quartzite | 96.50 | 0.42 | 0.96 | 0.90 | 0.16 | 0.92 |
| Cambrian quartzite (Utah) | 98.0 | 0.7 | 0.25 | 0.3 | trace | 0.2 |

For refractory purposes, the quartzite, to produce a physically strong brick should be hard, dense, and crush to splintery angular fragments of varied size and shape. The strength of the brick depends on the silica content of the rock; generally the silica content should not be less than 96% and the alkalies should not exceed 0.5%. $Al_2O_3$ and $Fe_2O_3$ are necessary to form a bond; their combined percentage is usually about 1.75% and should not exceed 2.5%. The melting interval of quartzite depends upon the contents of the bases and for good quartzite is cone 35 to 36 (1755°–1775° C.; 3191°–3227° F.).

Chemical analysis alone does not fully indicate the behavior of quartzite on heating. Material suitable for refractory purposes will not weaken or crack under high temperature. It shows perceptible expansion after the first firing, which is essentially unchanged by subsequent firings. Expansion is due to: 1. Expansion of the mineral itself; 2. Increase in porosity. Table 9 shows the volume increase due only to the first factor, calculated from the specific gravities of 3 samples each, of good quartzite and quartzite unsuitable for refractory purposes, heated repeatedly to 1450° C.

**Table 9.—Volume Increase, Percent, of Quartzite After Repeated Burnings**

| No. of firings | 1 | 2 | 3 | 4 | 5 |
|---|---|---|---|---|---|
| Good quartzite | 9.4 | 10.7 | 11.0 | 11.3 | 11.5 |
| Quartzite unsuitable for refractory purposes | 5.3 | 6.5 | 6.5 | 9.7 | 10.7 |

**Table 10.—Typical Analyses of Silica Brick**

| Raw Material | $SiO_2$ | $Al_2O_3$ | $Fe_2O_3$ | CaO | MgO | Alkalies |
|---|---|---|---|---|---|---|
| Medina quartzite (Penna.) | 95.9 | 1.0 | 1.0 | 2.0 | 0.10 | 0.10 |
| Baraboo quartzite (Wisconsin) | 95.1 | 1.3 | 1.2 | 2.1 | .20 | .20 |
| Weisner quartzite (Alabama) | 95.6 | 1.2 | 1.0 | 2.1 | .10 | .30 |
| Cambrian quartzite (Utah) | 96.35 | 0.6 | 0.5 | 2.2 | trace | ......... |

A paper by S. S. Cole, Effect of Firing at 1500° C. on Porosity and Specific Gravity of Quartzites (Am. Ceramic Soc., Refractories Div. Feb. 1931) contains a table giving descriptions and data covering quartzites in the U. S. and other countries.

The density of silica brick depends both upon the character of the quartzite used in its manufacture, and the temperature and duration of firing. The specific gravity of silica brick should lie between 2.28 and 2.40.

**EXPANSION OF SILICA BRICK.**—In manufacturing silica brick, permanent expansion occurs from the green brick size to the fired size. In service, under heat there is a further temporary expansion (often called thermal expansion) corresponding to the coefficient of expansion of silica, which disappears upon cooling. It is desirable that the permanent expansion be completed in the firing, but as the final increments of permanent expansion take place slowly under high temperature, silica brick will show a slight permanent expansion during reheating in service. (See Table 9.) The linear expansion in firing from green brick size to finished brick size ranges from 3.1% to 3.6%. The temporary expansion depends upon the temperature. The temporary expansion of Star silica brick tested at Mass. Inst. of Tech. at various temperatures was as follows:

| Temperature, deg. C. | 600 | 900 | 1200 |
|---|---|---|---|
| Temporary expansion | 0.7% | 0.9% | 1.1% |

The thermal expansion of well-burned silica brick amounts to 1.6% to 2.1%, the greater part of which occurs below 600° C.

In laying silica brick, it is important to provide for expansion at the rate of 1/8 to 3/16 in. per ft. Expansion joints should be kept free from mortar by packing to a depth of about 1 1/2 in., with a filler which will burn out, as sawdust, cardboard, or strips of wood.

Silica brick will not withstand rapid temperature changes. In both manufacture and service, heating and cooling must occur slowly and evenly, otherwise the brick will crack or spall.

**MAGNESITE BRICK.**—(Abstracted from "Magnesite Refractories," *Jour.* Am. Ceramic Soc., iii, No. 3, March, 1920, and from Basic Refractories for the Open Hearth, both by J. Spotts McDowell and Raymond M. Howe, *Bull.* No. 146, Feb., 1919, Am. Inst. of Min. Eng.) The chief use of magnesite is in the manufacture of refractory materials. Its chemical properties and high refractoriness make it highly suitable for furnace linings for metallurgical operations. For refractory purposes, it is sold in the form of bricks, of finely ground furnace magnesite for bricklaying, and of dead-burned grains for making and repairing furnace bottoms. The grains are a mixture of granules varying from 5/8 in. diameter to very fine but gritty particles.

**Table 11.—Typical Analyses of Crude Magnesites**

**Metalkase Magnesite Brick.**—Metalkase brick consist of round or square soft steel containers packed with ground dead-burned magnesite. They are used for the back walls, bulkheads and ends of basic open-hearth furnaces and side walls of electric furnaces. Their special advantage lies in the fact that the metal containers fuse for one or two inches back from the surface exposed to the heat, impregnate the magnesite and bind the entire face of the wall. Joints, which form channels for cutting action of the flame are thus eliminated and the life of the wall greatly extended. For dimensions, shapes, and other details, consult catalog of Harbison-Walker Refractories Co., Pittsburgh.

**CHROME BRICK.**—(Abstracted from Chrome Refractories, by J. Spotts McDowell and H. S. Robertson, *Jour.* Am. Ceramic Soc., v. No. 12, Dec., 1922.) Chromite ($FeO \cdot Cr_2O_3$) is the most nearly neutral chemically of all the common refractories. It is acted upon by either strong acids or by strong bases. Because of its neutral chemical character and high refractoriness it is an important refractory in metallurgical furnaces. Chromite deposits occur in Rhodesia, the Transvaal, New Caledonia, Turkey, India, Greece, Canada, Cuba, and Brazil, and in the U. S., in California, Oregon, Wyoming, Alaska, North Carolina, Maryland, and Pennsylvania. (See Table 11.) Ores of the approximate analyses in Table 12 are used in the U. S. as refractory materials.

## 2. PROPERTIES OF REFRACTORIES

(Arranged Alphabetically)

**ABRASION (Resistance to).**—Tests for resistance to abrasion have been rather unsatisfactory. No method so far devised has been generally regarded as sufficiently reliable to warrant adoption as standard.

**COLD CRUSHING STRENGTH** of various types of refractories is given by J. Spotts McDowell (*Blast Furnace and Steel Plant*, Oct. and Nov., 1923). See Table 15.

**CONDUCTIVITY, THERMAL.**—Table 16 gives the approximate thermal conductivities of various refractories over a wide range of temperatures.

**EXPANSION, THERMAL.**—The linear expansion of refractory brick, for various types of refractories, is given in Table 17. The figures given represent average values for total expansion of brick from room temperature to the temperatures indicated.

**LOAD, RESISTANCE TO, AT HIGH TEMPERATURE.**—The behavior of refractory brick of various types under load at high temperature is indicated in Table 18.

**MODULUS OF RUPTURE.**—Average values of modulus of rupture of various types of refractory brick are given in Table 19.

**Table 15.—Cold Crushing Strength of Refractories**

Cold crushing strength in lb. per sq. in.; average values; bricks tested on flat

| Fireclay Brick | | | | High-alumina Brick 70% $Al_2O_3$ | Silica Brick | Magnesite Brick | Chrome Brick |

| High heat duty (Siliceous) | 400 | Magnesite | 1500 |
| | | Chrome | 1600–2000 |

**POROSITY.**—The porosity of refractories depends upon various factors, among them the character and quality of raw material, the grind, the water content at time of molding, the pressure of molding, and the time and temperature of firing. The porosity in turn affects the resistance of the brick to temperature change, the rigidity under load at high temperatures, the thermal conductivity, and the resistance of the brick to abrasion and slag action. For a method of test for porosity and permanent volume changes in refractory materials, adopted as standard, see A.S.T.M. Designation C20–33. Porosities of various types of refractory brick are given in Table 20.

**Table 20.—Porosities by Volume, Average Values**

| Type of Brick | Process of Manufacture | Porosity, percent | Type of Brick | Process of Manufacture | Porosity, percent |
|---|---|---|---|---|---|
| Fireclay | | | High-alumina | | |

| High heat duty (Siliceous) | Hand or machine | 30 | Chrome | Machine | 20–30 |

**PYROMETRIC CONE EQUIVALENT** (P.C.E.).—See p. 5–03.

**REFRACTORINESS.**—(See Pyrometric Cone Equivalent.)

**RESISTIVITY (ELECTRICAL).**—Fig. 2 showing the approximate electrical resistivity of refractory brick was prepared from the results of Hartman, Sullivan and Allen (*Trans.* Am. Electrochem. Soc., vol. xxxviii, 279, 1920).

**RESISTIVITY (THERMAL).**—Thermal resistivity is the reciprocal of Thermal Conductivity. See Report of the Committee on Heat Transmission of the National Research Council on Definitions, Nomenclature, Symbols and Units for Heat Transmission.

**SLAGGING (RESISTANCE TO).**—This property is of prime importance in selection of refractory brick for service in furnaces where they are subjected to chemical corrosion by molten slags or fluxes. The resistance of a refractory brick to slag action depends on its chemical composition, density and porosity, the prevailing temperature and the chemical characteristics of the slag or flux. To resist acid slags or fluxes, fireclay brick, high-alumina brick or silica brick are serviceable. Where basic slags or fluxes are present, either fireclay, high-alumina, magnesite, or chrome brick are serviceable, the selection depending upon conditions stated above. Various simulative service tests have been devised, but as slagging depends on many factors no test as yet developed (1936) has proved sufficiently reliable to warrant its adoption as standard.

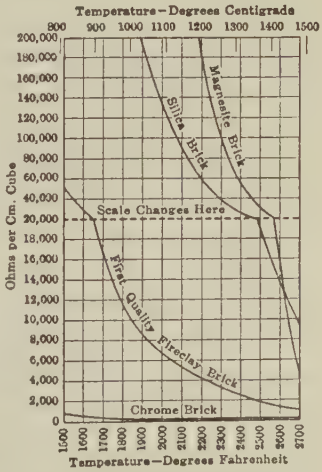

Fig. 2. Electrical Resistivity of Refractory Brick

**SPALLING, RESISTANCE TO.**—Spalling is defined as breaking or cracking of refractory brick in service to such an extent that pieces are separated or fall away, leaving new surfaces of the brick exposed. Spalling is of four types: 1. *Thermal Spalling*, caused by rapid expansion or contraction of the brick, due to rapid temperature changes. 2. *Textural Spalling* or changes in the texture or mineral constitution of the hot end of a brick, due to heat or the absorption of slags or fluxes, resulting in the formation of different zones between inner and outer brick surfaces. The physical properties of the zones may differ from each other and from the original brick, causing the inner end of the brick to crack and fall off, due to shrinkage cracks, unequal thermal expansion between zones, increased sensitiveness to temperature change, or other causes. 3. *Mechanical Spalling* or shattering of the brick by abuse in removal of slag or clinker, or by pinching due to thermal expansion or other causes. Pinch spalling is frequent in spring arches. 4. *Structural Spalling* due to improper design of brick shapes, faulty design or construction of the furnace, or excessive insulation that increases the severity of furnace conditions. Any of these may cause spalling of the first three types.

Of the five general types of refractory brick most widely used, super-duty fireclay brick have the greatest resistance to thermal spalling. High-alumina brick are only slightly less resistant. High-alumina brick may be considerably more resistant to textural spalling than other fireclay brick in the presence of certain types of slag. This is due to their high refractoriness and chemical composition which enable them to resist change in texture due to high temperature or slag action. Silica brick are extremely sensitive to temperature change in the range of 390° to 1110° F. Magnesite and chrome brick also are very sensitive to temperature change, although changes in manufacturing methods are improving this characteristic. No single method for determining resistance to spalling can be applied to all types of refractory brick. Various methods have been devised but none has been generally accepted as satisfactory. A method of control test for resistance of fireclay brick to thermal spalling is covered by A.S.T.M. Designation C38–36.

**SPECIFIC GRAVITY** of various types of refractories is given in Table 21.

For information concerning the determination of specific gravity see A.S.T.M. Designation C20–33T.

**SPECIFIC HEAT.**—The data in Table 22 are from Modern Refractory Practice, published by Harbison-Walker Refractories Co. Additional information is given in The Heat Required to Fire Ceramic Bodies by A. Ernest MacGee, *Jour.* Am. Ceramic Soc., vol. ix, p. 206 (1926) and in a supplementary article of the same title by H. E. Simpson, *Jour.* Am. Ceramic Soc., vol. x, p. 897, 1927.

## 3. MORTARS FOR LAYING REFRACTORY BRICK

Until comparatively recent years all fireclay brick were laid with fireclay mortar. It was the general opinion that the raw or unfired clay used for the purpose should have a refractoriness one to two cones lower than that of the brick with which it was used, in order that the joint material would be partially vitrified and thus bond the brick firmly together. Silica clay served for laying silica brick, finely ground dead-burned magnesite, known as furnace magnesite, for magnesite brick, and finely ground chrome ore, known as furnace chrome, for chrome brick.

**Table 21.—Specific Gravity of Various Types of Refractories**

| Type of Brick | Specific Gravity | | | Type of Brick | Specific Gravity | | |
|---|---|---|---|---|---|---|---|
| | High | Low | Average | | High | Low | Average |
| Fireclay | | | | High-alumina | Somewhat higher than for super-duty fireclay | | |
| Super-duty | 2.80 | 2.70 | 2.75 | Silica | 2.40 | 2.28 | 2.35 |
| High heat duty (Aluminous) | 2.75 | 2.65 | 2.70 | Magnesite | 3.60 | 3.44 | 3.52 |
| High heat duty (Siliceous) | Somewhat lower than for aluminous fireclay | | | Chrome | 4.4 | 3.7 | 4.05 |

**Table 22.—Specific Heats of Refractory Materials**

| Temp., deg. C. | 0 | 100 | 200 | 300 | 400 | 500 | 600 | 700 | 800 | 900 | 1000 | 1100 | 1200 | 1300 |

| Silica brick | .169 | .189 | .210 | .230 | .236 | .245 | .248 | .253 | .258 | .262 | .266 | .269 | .272 | .275 |
| Magnesite brick | .208 | .220 | .232 | .241 | .248 | .254 | .260 | .265 | .269 | .274 | .278 | .282 | .287 | .292 |
| Chrome brick | .170 | .177 | .182 | .188 | .193 | .198 | .202 | .206 | .210 | .213 | .217 | .220 | .222 | .224 |

**FIRECLAY MORTARS.**—(Raymond M. Howe, *Chem. & Met. Engg.*, Aug. 11, 1920.) Common practice in the making of firebrick mortars is to add certain materials to ground fireclay to make the mortar set firmly without the application of heat, or to cause it to burn to a dense structure by reason of decreased refractoriness. Ground silica and alumina are often added, and since clay itself is composed almost entirely of these materials, this is legitimate, and the general properties of plastic clay are often improved thereby. The addition of other materials is not justified and their effect is shown in Table 23.

The figures in this table were obtained from a series of experiments on columns and arches subjected to varying degrees of heat. The brick forming these columns and arches were laid in mortars of the compositions indicated in the table. The point of fusion given in the table is the point at which the mortar flowed between the joints.

In addition to the substances given in the table, ground bats were added to the mortar in another series of experiments, and their influence upon the fusion-point of the mortar was as follows:

| | | | | |
|---|---|---|---|---|
| Percentage of ground bats in mortar.... | 0 | 25 | 50 | 75 |
| Fusion-point, Cone No............. | 30 | 30–31 | 31 | 31–32 |
| Fusion-point, deg. C............... | 1730 | 1740 | 1750 | 1760 |

The addition of these ground bats is, in effect, an addition of clay of the same quality as that forming the mortar, but which has previously been shrunk. It accomplishes the same result in avoiding shrinkage of mortar as the addition of the substances in Table 23, but without their harmful effects.

**BONDING MORTARS.**—Until recently (1936) the term high-temperature cement designated various refractory products now known as high-temperature bonding mortars used in furnace masonry to bond refractory brick. Some of these will set and develop great strength merely upon air drying. Others do not develop any considerable strength until heated. Still others require very high temperatures to fully develop their bond. There is also considerable variation in the refractoriness of bonding mortars now on the market. They include a wide range of base materials. Consequently, their properties vary considerably. Care is necessary in selection to obtain satisfactory results.

Certain advantages over fireclay are claimed for high-temperature bonding mortars, as follows: 1. Increased resistance to erosion by mechanical action of molten metal, slag, or dust-laden gases moving at high velocity. 2. Greater resistance to chemical corrosion by slags and fluxes. 3. Increased resistance to abrasion. 4. Decreased permeability to gases, liquid metal, and slag. 5. More rigid construction. 6. Greater resistance to spalling.

## 4. COMMERCIAL FIREBRICK

A straight 9-inch firebrick weighs 7 lb.; a silica brick, 6.2 lb.; a magnesia brick, 9 lb.; a chrome brick, 10 lb.

Clay brick expand or shrink, depending upon the proportion of silica to alumina contained in the brick; but most fireclay brick contain alumina sufficient to show some shrinkage.

**Table 23.—Effect of Addition of Various Substances on Fusion-point of Fireclay Mortar**

| 50 | 50 | ...... | ...... | ...... | ...... | ...... | ...... | ...... | ...... | ...... | ...... | 29 | 1710 |

One cubic foot of wall requires 17, 9-in. bricks and weighs from 125 to 140 lb. One square foot of wall requires the following bricks: 4 1/2-in. wall, 7 9-in. straight bricks; 9-in. wall, 14 bricks; 13 1/2-in. wall, 21 bricks. Closely stacked, 1000 bricks occupy 56 cu. ft.; loosely stacked, 72 cu. ft. Where keys, wedges, and other "shapes" are used, add 10%, in estimating the number required.

To obtain the best results, firebrick should be laid in the same clay from which they are manufactured. From 400 to 600 lb. of fireclay should be sufficient to lay 1000 ordinary bricks. It should be used as a thin paste and not as mortar. The thinner the joint the better the furnace wall. Silica brick should be laid in silica cement and with the smallest joint possible.

Tables 24–28 give data on the commercial sizes and applications of fireclay and silica brick and block.

## 5. MISCELLANEOUS REFRACTORIES

**SILICON CARBIDE REFRACTORIES.**—(Data supplied by the Carborundum Co., Refractory Div., Perth Amboy, N. J.) Silicon carbide is composed of carbon and silicon, the chemical formula being SiC. It is made in the electric resistance furnace and sold under trade names of Carborundum, Crystolon and Carbolon. The crystalline product forms at 3344° F. and dissociates into its elements at 4064° F. No softening or fusion occurs below the dissociation temperature. Its hardness is 9.6 on the Moh scale, giving a remarkable resistance to abrasion. It is inert to all acids, liquid or gaseous, excepting a mixture of hydrofluoric and nitric acids, but may be decomposed by alkali when subject to high temperature. Silicon carbide reacts with basic slags and molten iron and steel. It is made into refractory brick and shapes of two types known as bonded and recrystallized.

Bonded SiC refractories comprise silicon carbide crystals bonded with small percentages of permanent binders, depending on the type of service. The standard 9 × 4 1/2 × 2 1/2 in. brick weighs approximately 9.25 lb. A wide variety of special shapes are made for use in boiler, heat treating, malleable iron annealing, forge and melting furnaces, soaking pits, recuperators, electric furnaces, zinc retorts, coking and calcining retorts, gas

producers, water gas generators, porcelain enameling furnaces, periodic and tunnel kilns, glass lehrs, rotary kilns, roasting furnaces, etc. SiC refractories are especially resistant to the destructive action of clinker formed from coal ash. Thermal conductivity of the higher grades of SiC refractories averages 108 B.t.u. per sq. ft. per 1 in. thickness per deg. F. per hr. in the temperature range 1200°–2800° F., making them suitable for indirect heating, as in muffles, retorts, recuperators, etc. Other average physical properties are: Modulus of rupture, 900 lb. per sq. in. at 2462° F.; crushing strength at 2462° F., 10,000

‡ Fireclay only.

lb. per sq. in.; at 68° F., 15,000 lb. per sq. in. Specific heat, 0.18. Spall resistance, higher than any other refractory.

Recrystallized refractories consist of a dense mass of SiC crystals bonded together by a recrystallization process. Since these bricks contain no added bonds they have essentially the same refractoriness as silicon carbide itself. They have little tendency to crack and spall and are used in extremely high temperature ranges where great load-carrying capacity is essential.

**ACID-RESISTING BRICK.**—Chemical process industries, and other industries where various acids are manufactured or are used in large quantities, require storage tanks, towers, and other types of acid equipment for which linings and packing material with acid-resisting properties are necessary. Lead, wood, asphalt, ordinary vitrified brick, chemical stoneware and special acid-resisting refractory brick have wide application, especially acid-resisting refractory brick. Such brick are serviceable both in contact with

acids and other liquid solvents, and in conjunction with nascent gases and acid fumes at high temperatures.

**Duro**, an acid-resisting refractory brick, manufactured by Harbison-Walker Refractories Company, Pittsburgh, Pa., is dense, vitreous, non-absorbent, of low porosity, and strongly resistant to the action of solvents. It is manufactured from materials of extremely low flux content. The brick are fired at exceedingly high temperatures, which convert the constituents largely into crystalline minerals, which are insoluble in acids and corrosive acid chemical solutions, and highly resistant to concentrated alkali solutions. Duro is highly insoluble in mineral and organic acids of any degree of concentration, and at practically all working temperatures. It is well adapted for service in processes with temperatures up to 2400° F. in conjunction with nascent gases and acid fumes, and it has high mechanical strength.

**DIGESTER BRICK.**—The largest source of raw materials for the manufacture of paper pulp is soft wood, although other materials are used such as rags, straw, waste fibers, bamboo, jute, bagasse (waste sugar cane) and esparto (wild grass). Wood is transformed into paper pulp by either mechanical or chemical methods. One of the latter, known as the sulphite process, comprises boiling wood chips in sulphite liquor, which consists mainly of calcium and magnesium bisulphates dissolved in sulphurous acid. This process is accomplished in steel tanks called digesters. Formerly, digesters were lead lined, but in present practice the lining is a 2-in. thickness of Portland cement and sand against the shell and a double lining of acid-resisting brick, with a cement-sand mixture, 1-in. thick, between.

Widely used types of digester brick are such as are made by Fiske Brick and Granule Company, Boston, Mass. One type is exceedingly dense and impervious; another is of a slightly more open texture. The dense vitreous brick often is preferred for the back lining, with the more open texture brick for the face. The face brick readily becomes impregnated with solids and after a short time in service is quite impervious. The open texture type is more resistant to spalling conditions, but depending upon the practice, the dense impervious brick frequently is used to good advantage for both the face and back linings. For certain digester conditions, a still more open texture brick is made. This is exceptionally resistant to spalling but can be used to advantage only in operations where the pores become filled with organic constituents and their salts.

**FORSTERITE BRICK.**—Forsterite refractories are made from olivine rock to which magnesia is added in manufacture. Their chief constituent is forsterite ($2MgO \cdot SiO_2$), the brick analyzing about 57% MgO, 32% $SiO_2$, 6% FeO, 5% other oxides. Forsterite refractories are considered to be semi-basic, and are stable in volume at high temperatures. Their thermal conductivity is less than that of magnesite brick and approximates that of silica brick. Steam or aqueous acids will attack them.

Forsterite brick are used in ports, bridge walls, division walls, uptakes and bulkheads of basic open-hearth steel furnaces, and in exposed sections of side walls in copper reverberatory and refining furnaces. Their ability to carry load at relatively high temperatures has made them suitable within a certain temperature range for suspended and sprung arch roofs on copper reverberatory and refining furnaces and on copper holding furnaces.

**INSULATING BRICK.**—Thermal insulation is used to increase the operating efficiency of industrial furnaces. The materials available for this purpose may be classified as (1) bulk insulation, (2) insulating brick, (3) insulating refractory brick.

1. Bulk insulation, in the form of diatomaceous earth powder or expanded vermiculite, is used as an insulating backing to refractory settings, especially for irregular surfaces where brick cannot be readily fitted.

2. Insulating brick have high insulating values but are not suitable for use where they may be exposed to flame or products of combustion. They are manufactured from diatomaceous earth or other materials having inherently low thermal conductivities and are used mainly as a backing for refractory brick settings to reduce heat losses.

3. Insulating refractory brick usually are made from selected fireclays, which are given open porous structure by "chemical bloating," or by the addition of organic materials which burn out during the firing process. Insulating refractory brick can be used in contact with flame or combustion gases, but will not withstand slag action or mechanical abrasion.

Insulation of a refractory setting reduces the heat flow and raises the mean temperature of the wall. This may necessitate the use of a more refractory material for the setting and always increases the amount of heat stored in it. Where high heat capacity is undesirable, a lining of insulating refractory brick may be used in place of a combination of refractory brick and an insulating backing. Insulating refractory brick ordinarily weigh only 30 to 40% as much as refractory fireclay brick of the usual density, and their heat capacity is only 30 to 40% as great. Therefore, when conditions permit their use, they promote maximum thermal efficiency in intermittently operated furnaces. For additional information on heat insulation see Kent's Mechanical Engineers' Handbook—Power, pp. 3–54 to 3–71, forming Vol. 2 of this series.

## 6. APPLICATIONS OF REFRACTORIES

The applications of the common types of refractory brick and of insulation in the construction of furnaces are given in Table 28. In some cases the refractories specified appear to be conflicting. However, since furnace design and operating conditions vary widely, the requirements of the refractories also will vary. The recommendations given in the table are for general guidance, and manufacturers of refractories should be consulted for recommendations for specific conditions.

**Table 28.—Applications of Refractory Brick and Insulation**

Types of Brick

| | | |
|---|---|---|
| 1. Fireclay Brick | 2. High-alumina Brick | 3. Silica Brick |
| 1–A Super-duty | 2–A 50% alumina class | 4. Magnesite Brick |
| 1–B High heat duty | 2–B 60% alumina class | 5. Chrome Brick |
| 1–C Intermediate heat duty | 2–C 70% alumina class | 6. Insulation |
| 1–D Moderate heat duty | 2–D 80% alumina class | 6–A Insulating refractory brick |
| 1–E Low heat duty | | 6–B Insulating brick |

| Type of Furnace | Application | Kinds of Brick Used (alone or in combination) |

## WOOD

**PROPERTIES OF WOOD.**—The composition of absolutely dry wood is given in Bull. 73 of the U. S. Dept. of Agriculture as: Carbon, 49%; oxygen, 44%; hydrogen, 6%; ash, 1%. The proportions of these several elements vary slightly in the different varieties, and the presence of various oils and pigments will cause a variation in the heating values of the several species of as much as 22%. Heating values range from 5400 to 6800 B.t.u. per lb. For more detailed information on the composition and heating value of wood see Kent's Mechanical Engineers' Handbook—Power, p. 4–41, forming Vol. 2 of this series. Table 1 gives the specific gravity and weight of the various varieties of wood.

Table 2 gives the approximate commercial measures and weights of wood. For data on the strength of wood see pp. 7–28 and 7–37 of this book.

**CHARACTERISTICS AND USES OF THE VARIOUS WOODS.**—The woods most generally used in industry are as follows:

**Ash.**—A heavy, hard, coarse-grained wood. The white ash is compact and elastic, and is used for interior and cabinet work, but is not suitable for structural work. The red and green varieties are brittle, and are used as a substitute for the white ash.

**Balsa.**—An extremely light wood, used for heat insulation. When waterproofed, it is used for life preservers.

**Table 1.—Specific Gravity and Weight of Wood**

| Kind of Wood | Specific Gravity | | Wt., lb. per cu. ft. | Kind of Wood | Specific Gravity | | Wt., lb. per cu. ft. |
|---|---|---|---|---|---|---|---|
| | Range | Aver. | | | Range | Aver. | |
| Acacia | 0.58–0.85 | 0.72 | 45. | Hornbeam | 0.75 | 0.75 | 47. |
| Alder | .42– .68 | .54 | 34. | Juniper | .56 | .56 | 35. |
| Apple | .66– .84 | .75 | 47. | Lancewood | 0.68–1.00 | .84 | 52.4 |
| Arbor Vitæ | ...... | .55 | 34.3 | Larch | .50– .56 | .54 | 33.6 |

| Sycamore | .......... | 4750 | 3000 | .......... |
| Walnut | .......... | 4900 | 3800 | .......... |

**Butternut.**—A light, coarse-grained, soft, compact wood that is easily worked and takes a high polish. Used for interior finish.

**Cedar.**—The red variety is compact and brittle, but easily worked. Its characteristic odor is repellent to insects, and it, therefore, is used as a lining for vermin-proof closets and chests. The white variety is soft, compact and resistant to decay when in contact with the soil, but it is low in strength and toughness. Both varieties are used for posts, sills, fencing, and shingles.

**Chestnut.**—A coarse-grained, soft, light wood, easily worked, and weather resistant. Used for heavy construction, interior finish, railroad ties and telegraph poles.

**Cypress.**—A close-grained, durable, light, hard, brittle wood, that is easily worked and takes a high polish. Resistant to moisture. Used for trestles, docks, building construction, shingles, interior finish and cabinet work.

**Douglas Fir.**—A hard, strong, durable wood, but difficult to work. Used for all kinds of construction.

**Elm.**—A close-grained, hard, heavy, tough wood, capable of high polish. Difficult to work, and warps badly in drying. Used for car, wagon, boat and shipbuilding, and for bridge timbers, sills, ties, and furniture.

**Gum.**—A close-grained, heavy, hard, tough wood, that tends to warp and shrink in seasoning. Not resistant to weather. Takes a high polish. Is used in furniture manufacture.

**Hemlock.**—A coarse-grained, light, soft, brittle wood that splits easily, and which is not durable under exposure. Used principally for crates and packing cases.

**Hickory.**—The heaviest, hardest, strongest and toughest of all American woods. Extremely flexible, and used for bent wood work. Not suitable for building construction.

**Lignum Vitæ.**—A very heavy, hard and resinous wood, difficult to work. Used for small turnings, tool handles and pulley sheaves.

**Locust.**—A close-grained, strong, heavy, hard wood, used for posts and turnings.

**Mahogany.**—A wood that in the green condition is strong, durable and flexible, but which is brittle when dry. Resistant to dry rot and worms. Used for interior finish, furniture, pattern-work and handrails.

**Maple.**—Both white and hard maple are fine-grained, heavy, hard, strong woods, used for flooring, interior finish and furniture.

**Oak.**—The white oak is heavy, hard, strong, tough and close-grained. Will take a high polish. Is used for framed structures, interior finish, furniture, shipbuilding and railroad ties. The chestnut oak is durable in contact with soil and is used for railroad ties. Red and black oak are used for interior finish, furniture and railroad ties.

**Palmetto.**—A light wood, durable under water and resistant to teredo attacks. Used principally for piling.

**Pine.**—The white pine is soft, straight grained, light, but of relatively low strength. It is easily worked and is used for interior finish and patternwork. Yellow pine, long-leaf variety, is a heavy, hard, coarse-grain, strong wood, durable when dry and well ventilated. It is used for heavy framing timbers and floors, but is subject to rapid decay in contact with ground. The short-leaf variety varies widely in quality and is used as a substitute for the long-leaf kind. The red, or Norway pine, is a coarse-grained, compact, light, hard wood, used for all purposes of construction.

**Poplar.**—A soft, close, straight grain, brittle wood. It shrinks excessively in drying, and warps and twists. It is easily worked and is used for general carpentry work.

**Redwood.**—A coarse-grained, light, soft, brittle, and easily worked wood, which is durable in contact with soil. Used for railroad ties, fence posts, telegraph poles, etc.

**Spruce.**—The Sitka spruce is light, soft, and of medium strength. It is used for structural purposes and in airplane framework. Red spruce is a close straight-grained, light, soft wood used for general construction and framing purposes; also for piles and other submerged construction. White spruce is similar to red; is used as construction lumber.

**Tamarack.**—A wood that is similar to pine in appearance and quality, and which is used for telegraph poles, railway ties, and shipbuilding.

**Walnut (Black).**—A coarse-grained, hard, heavy, strong wood used for interior finish and cabinet work.

**PRESERVATION OF TIMBER.**—Timber is treated to inhibit decay, usually by impregnating it with creosote. The creosote can be applied by soaking the wood in an open tank of creosote, or by subjecting it to a vacuum and pressure process which causes the creosote to penetrate the fibers more thoroughly. The quantity of creosote required to preserve timbers is approximately as follows: Hardwood railroad ties, 6–14 lb. per cu. ft.; softwood railroad ties, 13–20 lb. per cu. ft.; dimension timbers, 15–20 lb. per cu. ft.; piles, 20–30 lb. per cu. ft.

Zinc chloride sometimes is used as a substitute for creosote. Timbers treated with zinc chloride cannot be used in exposed locations or for submerged construction.

**Table 3.—Properties of American Standard Yard Lumber and Timber Sizes**

| Nominal Size in inches | American Standard Dressed Size, inches | Area of Section, sq. in. | Weight per lin. ft.,* lb. | Moment of Inertia, $I$, in.$^4$ | Section-Modulus, $S$, in.$^3$ |
|---|---|---|---|---|---|
| 2 × 4 | 1 5/8 × 3 5/8 | 5.89 | 1.6 | 6.45 | 3.56 |

**KILN DRYING OF LUMBER.**—See Kent's Mechanical Engineers' Handbook—Power, p. 3–52, forming Vol. 2 of this series and also pp. 22–17 to 22–21 of this book.

**YARD LUMBER AND TIMBER SIZES.**—Table 3 gives the dressed size of American standard yard lumber and timber, together with some of the properties.

**PLYWOOD** consists of an odd number of thin layers of wood glued together, the grain in the alternate layers being at right angles. A characteristic of plywood is that the strength is approximately equal in all directions, and is approximately the mean of the strength with and across the grain. See Table 4 for the tensile strength of plywood. Plywood is made usually from basswood, birch, maple, poplar, redwood and red gum.

**Table 4.—Tensile Strength of Plywood**

(U. S. Forest Products Laboratory, Madison, Wis.)

| Species | Weight of Plywood, Kiln-dry, lb. per cu. ft. | Moisture at Test, percent | Tensile Strength of 3-ply Plywood Parallel to Grain of Faces lb. per sq. in. | Tensile Strength of Single-ply Veneer, Parallel to Grain, lb. per sq. in. |
|---|---|---|---|---|
| Basswood | 28 | 9.2 | 6,900 | 10,300 |
| Yellow Birch | 45 | 8.5 | 13,200 | 19,800 |
| Maple, soft | 38 | 8.9 | 8,200 | 12,300 |
| " hard | 46 | 8.0 | 10,200 | 15,300 |
| Yellow poplar | 34 | 3.4 | 7,400 | 11,100 |
| Red gum | 36 | 8.7 | 7,800 | 11,800 |
| Redwood | 28 | 9.7 | 4,800 | 7,200 |

## CORK

Cork is the spongy outer bark of the cork oak tree, which grows principally in Spain, Portugal and Northern Africa. It is of cellular structure, each cell comprising a strong, impenetrable skin, enclosing air.

**NATURAL CORK.**—The uses of natural cork are limited by the variability of the raw material, by structural flaws, which are uncontrollable in a natural material, and by the irregularity in size, thickness and shape. These limitations can be overcome by laminating the corkwood to produce a material of greater uniformity and structural strength.

**CORK COMPOSITIONS.**—Finely ground cork combined with various binders form materials having all the desirable basic qualities of natural cork. Composition can be made to provide for expansion or contraction, and to be fabricated into sheets, discs, tubes, blocks, rings, strips, balls, wheels, rods and irregularly shaped articles. It also can be molded directly to the desired pattern. Composition is laminated with cloth, vulcanized fiber, or other material to increase the tensile strength. Cork also has been combined with rubber and synthetic resins.

**PROPERTIES OF CORK.—1. Resistance to Liquid Penetration.**—Cork is highly resistant to penetration by liquids. Since it is not fibrous, liquids are not drawn through it by capillarity.

**Compressibility.**—Prolonged compression, under heavy loads, will cause little permanent deformation. Eight small pieces of cork composition $^7/_8$ in. thick, used as cushions between journal box and the car body of railway cars, supporting approximately 120,000 lb., after one year were still resilient, with a reduction of total thickness of only $^1/_8$ in.

**Resilience.**—Long subjection to pressure does not destroy the structure or resiliency of cork. It will not harden or deteriorate under normal conditions.

**Buoyancy.**—Natural cork, with a specific gravity of 0.15 to 0.20, is generally used for floats or other devices requiring buoyancy.

**Thermal Conductivity.**—The air-cell structure of cork forms an excellent insulator. It is highly resistant to charring and ignition. At about 250° F., slow distillation begins and the cork discolors slightly. It does not ignite except in contact with flame, and it burns only as long as flame is applied from an external source. Combustion produces a carbonized coating which retards further burning.

**Chemical Inertness.**—Cork resists chemical action better than most natural materials, and can be safely used in contact with most chemicals. In industrial processes it does not corrode, discolor, or deteriorate and is not affected by oil, grease, gasoline, or other petroleum products. Alkalis, certain acids and organic solvents have a destructive action, and, as a rule, cork should not be used in contact with them. Iron solutions sometimes react with the natural tannin in the cork to cause the surface discoloration, which does not affect the properties of the cork.

**Stability.**—Cork retains its initial properties practically unimpaired under all conditions of temperature, humidity or other atmospheric conditions. Its compressibility and resilience enable it to withstand abrasive wear.

**Frictional Properties.**—The coefficient of friction of natural cork and compositions is higher than that of most materials used for friction. This coefficient is not materially decreased by the presence of moisture, oil or grease. Compositions are more extensively used, as it is possible to control, within reasonable limits, their coefficient of friction. The softer compositions have the higher coefficients of friction, but dense materials for severe conditions have a sufficiently high coefficient for ordinary work. See Table 1 for coefficient of friction of cork and cork compositions.

**Table 1.–Angle of Repose and Coefficient of Friction of Leather and Cork**

(Armstrong Cork Co.)

| | Angle of Repose, $\theta$ | Coefficient of Friction, $f$ | $1 \div f$ |

**USES.**—The following paragraphs give the principal uses of cork and cork products:

**Seals.**—Gaskets for sealing and cushioning, and for sealing anti-friction bearings. While cork closures are sometimes made as split rings, the continuous ring generally is used. Cork seals should not be distorted either in assembling or in use. They are not recommended for assembly in internal grooves and must be lubricated before assembly, with graphite grease thinned with lubricating oil to the consistency of vaseline. Cork gaskets should not be used on steam or other high-temperature connections or in contact with strong alkaline solutions, such as ammonia.

**Cushioning** between adjoining surfaces of metal and glass; metal and porcelain or other similar combinations; automobile bodies; to deaden vibration in machinery.

**Friction.**—In the textile industry for drawing yarn and cloth through machines; friction drives; clutches; feed rolls for machines handling paper, cloth, foil, etc.

**Floats.**—Gage mechanisms; carburetors; dispensing pumps for oil and gasoline.

**Insulation.**—Under roofs to reduce heat losses and to lessen condensation and eliminate ceiling drip; pipe covering for drinking water, brine and ammonia lines, and cold lines in the oil refining and chemical industries.

**Natural Cork Products.**—Bottle corks; wheels for polishing glass; floats for carburetors and gages; handles for tools and instruments; discs, washers, and gaskets for various applications; life preservers; yacht fenders; cork balls; paper.

## RUBBER *

Rubber is used in industry for machinery mountings, for bumpers and springs, for the absorption of vibration, for the lining of tanks, and many other purposes.

**PHYSICAL PROPERTIES.**—The physical properties of various grades of rubber are given in Table 1. The heat of combustion of crude rubber is 19,300 B.t.u. per lb. The electrical resistivity depends on temperature and the character of the rubber stock, decreasing perhaps several thousand times with increase of temperature from room temperature to 212° F. Depending on the rubber stock, it may range from $1 \times 10^8$ to $200 \times 10^8$ megohm per sq. cm. per cm. length. The dielectric constant (air = 1) ranges usually from 2.5 to 4.5. The electric breakdown stress ranges from 1 to 60 kilovolts per millimeter thickness. Rubber should not be mechanically worked at temperatures above 180° F.

**Table 1.—Physical Properties of Rubber**

All values based on room temperature

| Stock Number | 5140 | 5488 | 5638 | 5255 | 5691 | 5623 |
|---|---|---|---|---|---|---|
| Property | | | | | | |
| Hardness (Shore Durometer) | 30 | 40 | 50 | 60 | 70 | 80 |
| Elastic modulus for static compression, lb. per sq. in. | 185 | 270 | 375 | 550 | 750 | 1200 |
| Shear modulus (static), lb. per sq. in. | 55 | 83 | 110 | 132 | 190 | .... |
| Volume compression at 1000 lb. per sq. in. pressure, percent | 0.34 | 0.31 | 0.29 | 0.27 | 0.24 | 0.22 |
| Specific gravity | 1.01 | 1.06 | 1.11 | 1.18 | 1.25 | 1.31 |
| Specific heat | 0.47 | 0.43 | 0.40 | 0.38 | 0.35 | 0.33 |
| Thermal conductivity in B.t.u. per sq. ft. per sec. for a temp. gradient of 1° F. per in. | 0.00027 | 0.00029 | 0.00030 | 0.00032 | 0.00035 | 0.00037 |
| Cubical expansion with temperature, percent change in unit volume per deg. F. | 0.00033 | 0.00029 | 0.00026 | 0.00024 | 0.00022 | 0.00020 |
| Velocity of sound in rubber rods, ft. per sec. | 115 | 165 | 210 | 345 | 750 | .... |
| Shrinkage in linear dimensions of the cured rubber piece* | 2.2 | 2.0 | 1.7 | 1.5 | 1.4 | 1.3 |

* With respect to its mold cavity, both at room temperature.

## 1. ACTION OF RUBBER UNDER STRESS

In determining the action of rubber under stress, the fatigue characteristics and working temperature must be considered as well as the load. In general, compression strain† should not exceed 15 to 20%, and with hard stock should not exceed 5%.

**ELASTIC MODULUS.**—Rubber does not exactly follow Hooke's law (see p. 7–04). The elastic modulus in compression may be approximately expressed as

$$E = (F/A_o)\{h/(h_o - h)\} = (F/A)\{h_o/(h_o - h)\} \qquad [1]$$

where $E$ = elastic modulus in compression, lb. per sq. in.; $F$ = compression load, lb.; $A_o$ and $A$ = respectively, original no-load and compressed cross-sectional area, sq. in.; $h_o$ and $h$ = respectively original and compressed height, in., under load $F$. These relations apply only to blocks where the rubber can expand freely in a direction perpendicular to the direction of the applied load, *i.e.*, to blocks whose faces have been lubricated with glycerine or soap solution. For soft stocks (30 Shore durometer) these relations will hold up to 50% compression; for hard stocks (80 Shore durometer) they probably are incorrect beyond 15% compression. In determining $E$, the block must be subjected to at least five complete compression cycles before readings are taken.

**Relation of Elastic Modulus in Compression to Hardness.**—Hardness is measured by means of the Shore durometer, which gives the ratio of a constant indenting force to the indentation of a small flat-tipped tapering needle. The readings are given in terms of an arbitrary scale, running with increasing hardness from 0 to 100. The relation of durometer hardness to elastic modulus is only approximate, as the reading of the former often is a function of the observer and the size of test piece. Further, elastic modulus will vary with the calendar direction of the grain, which variation may be as large as 10%. Table 2 shows the approximate relation between durometer hardness and elastic modulus in compression and in shear for several grades of rubber.

---

* The data herein given are abstracted, by permission, from a treatise entitled The Physical Properties of Rubber, issued by U. S. Rubber Products, Inc., Detroit.

† Strain, as here used, is the ratio of deflection under stress to the original thickness.

Table 2.—Relation between Durometer Hardness and Elastic Modulus

| Stock No. | 5140 | 5488 | 5638 | 5255 | 5691 | 5623 |
|---|---|---|---|---|---|---|
| Durometer hardness | 30 ± 3 | 40 ± 4 | 50 ± 4 | 60 ± 4 | 70 ± 4 | 80 ± 4 |
| Elastic modulus in compression, lb. per sq. in. | 185 ± 30 | 270 ± 40 | 375 ± 50 | 550 ± 60 | 750 ± 100 | 1200 ± 300 |
| Elastic modulus in shear, lb. per sq. in. | 55 ± 7 | 83 ± 10 | 110 ± 15 | 132 ± 20 | 190 ± 25 | ...... |

**DECREASE OF VOLUME OF RUBBER UNDER COMPRESSION** is shown in Fig. 1 together with the decrease in volume of water. The values shown are those at 77° F.

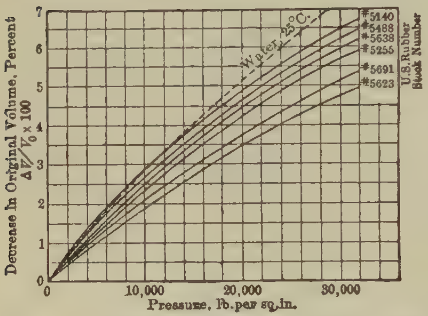

Fig. 1. Decrease of Volume of Rubber under Compression

**RUBBER SANDWICHES UNDER COMPRESSION.**—A rubber sandwich is a rubber block with two opposite faces adhered to metal plates. The compression under any load acting across the plates is a function of the dimensions and shape of the block, the elastic modulus of the rubber, the distribution of load over the surface of the block, the temperature, the amount of non-parallelism of the metal plate, the distance the plates extend beyond the side surfaces of the rubber and other variables. In general, sandwiches of the same relative dimensions and same elastic moduli are deflected the same percentage of their thickness by the same compression loads per unit area. Usually, it is not feasible to load a sandwich with more than 750 lb. per sq. in. static load, or to apply a load producing more than 20% deflection. An approximate value of the amount of compression may be obtained by means of the nomographic chart, Fig. 2.

**Use of the Nomographic Chart.**—Let $L$ = length, $W$ = width, $T$ = thickness, $F$ = total load, lb., and $P$ = unit pressure, lb. per sq. in., on a rubber sandwich. Draw a line from the point on the deflection scale representing the desired deflection, to the point on the pounds per square inch scale, corresponding to $P = F/A$, intersecting the line XX at $y$. Connect the points on the $L/W$ and $W/T$ scales corresponding to the ratios $L/W$ and $W/T$ of the sandwich under consideration, and project the line to the $Q/T$ scale. From the point so found on the $Q/T$ scale, draw a line through $y$ to intersect the $E$ scale, to find the modulus of elasticity in compression.

$Q/T$ is the ratio of the length of side of the sandwich under consideration to the thickness of a square sandwich which will be compressed the same percentage of its thickness by the same load per unit area. $Q$ is the length in the nomogram of a non-rectangular sandwich corresponding to $L$. Values of $Q$ for various shapes of sandwich are as follows.

**Solid Sandwiches.**—*Square* sandwich, $Q = W$; *rectangular* sandwich, $Q = L$; *cylindrical* sandwich of *circular* cross-section, $Q = 0.93 \times$ diam.; *cylindrical* sandwich of *elliptical* cross-section, major axis corresponds to nomographic $L$ and minor axis to nomographic $W$; *triangular* sandwich, $Q$ = diam. of inscribed circle.

**Doughnut Sandwiches** (sandwiches with hole).—*Square doughnut*, $Q = S - s$, where $S$, $s$ = respectively, length of a side of the sandwich, and the side or diam. of the hole; this relation holds for a circular hole whose diameter is small compared to the size of the sandwich.

*Circular doughnut* with circular hole, $Q = D - d$, where $D$, $d$ = respectively, diameters of sandwich and of hole.

*Rectangular* or *elliptical* sandwiches with central hole,

$$Q = Q_n - (W/L)d \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [2]$$

where $Q_n$ = value of $Q$ for a solid sandwich and $d$ = diam. or side of hole.

For a hole not in the center of the sandwich,

$$Q = Q_n - (W/L)\{r/(r + y)\}d \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [3]$$

where $r$ = distance from center of hole to edge of sandwich on a line passing through center of sandwich, and $y$ = distance from center of hole to center of sandwich, other notation as before. Relation [3] holds only for values of $d < (W/2)$.

The nomographic chart will give values of compression loads for a given stock number that will be accurate to within 25% of the deflection for values of $Q/T < 12$. For values of $Q/T > 12$, it is accurate only to within 50%.

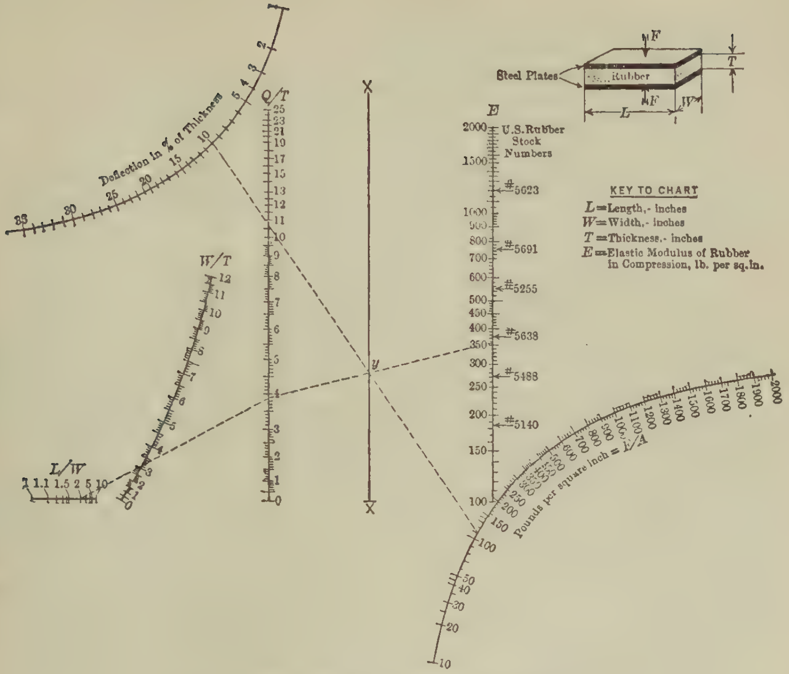

FIG. 2. Nomographic Chart for Rubber Sandwiches

EXAMPLE.—Determine the rubber stock number and durometer hardness of a rectangular rubber sandwich 1 in. thick, 6 in. long, 3 in. wide, to support a load of 2000 lb. with a deflection of approximately 10%. *Solution.*—$F/A = 2000/(6 \times 3) = 111.1$ lb. per sq. in. From the point corresponding to 111.1 on the pounds per square inch scale, Fig. 2, draw a line to point 10 on the deflection scale, intersecting XX at $y$. From the point $L/W = 6/3 = 2$ on the $L/W$ scale, draw a line to the point $W/T = 3/1 = 3$ on the $W/T$ scale, and extend it until it intersects the $Q/T$ scale at 3.9. From this point draw a line through $y$ and project it to intersect the $E$ scale at 360, which shows that the stock number to be used is 5638. Reference to Table 2 shows that stock No. 5638 corresponds to a durometer hardness of 50 ± 4.

**RUBBER IN SHEAR.**—Rubber sandwiches may be used in shear as a resilient mounting for heavy loads. Usually a double rubber sandwich is employed to balance out the rotational torque that would exist with a single rubber sandwich. The stress-strain relations in shear are given by the following formulas.

$$F/A = S(d/T), \text{ for values of } d/T = 0 \text{ to } 0.3 \qquad [4]$$

$$F/A = 0.9\,S(d/T), \text{ for values of } d/T = 0.3 \text{ to } 0.8 \qquad [5]$$

$$F/A = 0.833\,S(d/T), \text{ for values of } d/T = 0.8 \text{ to } 1.2 \qquad [6]$$

where $F$ = applied load producing shear, lb.; $A$ = area of sandwich, sq. in. = $L \times W$; $T$ = thickness of sandwich, in.; $d$ = deflection, in.; and $S$ = shear modulus (see Table 1). A more exact relation good up to 80% deflection in terms of $T$ is

$$F/A = S(\theta/57.3) = S\{\tan^{-1}(d/T)/57.3\} \qquad [7]$$

where $\theta$ = average angle of shear, deg. The shear in equations [4] to [7] may be used for sandwiches in shear with faces other than rectangular by replacing $(L \times W)$ with the area of one of the faces. If the two faces are not equal, $(L \times W)$ should be replaced with a value of one-half the sum of the area of the two faces. If lateral forces of tension or compression exist, equations [4] to [7] are approximately correct if $T$ is taken as the thickness when no lateral forces are applied. In general, metal-rubber bond should not be subjected to static stresses in shear greater than 25 lb. per sq. in.

**Angular Shear.**—Let $R$ = outer radius, $r$ = inner radius of a circular doughnut sandwich, in.; $T$ = thickness of sandwich, in.; $d_o$ = linear deflection, in., along the arc, of a point on the periphery at a distance $R$ from the center. $\theta$ = angular deflection of rotation, deg.; $S$ = shear modulus for the rubber, lb. per sq. in. $\tau$ = moment of couple or torque, lb.-in., producing angular deflection $\theta$. Then

$$\tau = \frac{\pi}{2}\,\frac{Sd_o}{T}\left[\frac{R^4 - r^4}{R}\right] = 0.0274\,(S\theta/T)/(R^4 - r^4) \quad . \; . \; . \; . \; . \; . \quad [8]$$

Maximum stress $f$ in the rubber will occur at radius $R$ where stress lb. per sq. in. is

$$f = S(d_o/T) = (SR/T)\,(\theta/57.3) \quad . \; . \; . \; . \; . \; . \; . \; . \quad [9]$$

For a given torque $\tau$ the dimensions of the sandwich must be such that $f$ is not too large. The most economical sandwich for a given torque and a maximum allowable value of $f$ is one in which the ratio $R/r = \sqrt{3}$.

## 2. GENERAL PROPERTIES OF RUBBER

**ABSORPTION OF LIQUID AND GASES.**—The amount and rate of absorption of water depends on the type of rubber, size of sample and its previous history. In general, amount of absorption increases from 1.2 to 2 times per 18° F. temperature rise, increases with amount of dissolved air and amount of aging. Repeated absorption with intermediate drying increases water-absorbing tendency. Water absorbed by thin rubber sheet samples ranges from 0.1% to 2%, by weight, in one day to 2% to 15% after one year. With thick samples the absorption is many times less.

The absorption of gas by rubber decreases, in general, with increase in temperature, and increases with increase in pressure. The absorption coefficient $C$ is the volume of gas, cu. cm. at 0° C. and atmospheric pressure, absorbed by one cu. cm. of rubber in equilibrium with the gas. Approximate values of $C$ for various gases, at room temperature, are:

| | | | | | |
|---|---|---|---|---|---|
| Hydrogen | $C$ = 0.01 | Air | $C$ = 0.12 | Nitrous oxide | $C$ = 1.6 |
| Nitrogen | = .04 | Methane | = .25 | Hydrogen sulphide | = 2.7 |
| Carbon monoxide | = .06 | Carbon dioxide | = 1.0 | Ammonia | = 10.0 |
| Oxygen | = .07 | Ethylene | = 1.4 | Sulphur dioxide | = 20.0 |

The value of $C$ for $CO_2$ will be halved, approximately, in going from room temperature to 120° F. above room temperature. A variation of pressure from 0.1 to 1 atmosphere will decrease the coefficient from 6 to 7 times.

**PERMEABILITY** is the amount of gas penetrating a unit area of rubber in unit time. It is proportional to the partial pressure of the gas on either side of the membrane and inversely proportional to its thickness. Permeability increases with increase in temperature. The specific permeability of hydrogen at normal temperature and pressure through rubber is approximately 0.000038 cu. ft. per day per sq. ft. per inch thickness per 1 atmosphere difference in pressure. The relative permeability of several gases is as follows, the permeability of hydrogen being taken as 1:

| | | | | | |
|---|---|---|---|---|---|
| Nitrogen | 0.16 | Oxygen | 0.44 | Ammonia | 8.0 |
| Air | 0.22 | Helium | 0.65 | Methyl chloride | 18.0 |
| Argon | 0.26 | Carbon dioxide | 2.9 | Water vapor | 50.0 |
| | | Nitrous oxide | 4.5 | | |

The variation with temperature of specific permeability $P$ of soft vulcanized rubber for hydrogen and carbon dioxide is as follows:

| Temperature 0° F. | 32 | 68 | 77 | 104 | 140 | 176 | 212 |
|---|---|---|---|---|---|---|---|
| Hydrogen, $P$ | = 0.12 | 0.30 | 0.34 | 0.57 | 1.02 | 1.68 | 2.60 |
| $CO_2$, $P$ | = 0.30 | 0.84 | 0.98 | 1.77 | 3.88 | 4.00 | 5.30 |

**ADHERENCE OF RUBBER TO METALS.**—Rubber may be bonded to metal with an ultimate bond strength of 400–500 lb. per sq. in. Such bonds are used in engine and motor mountings to absorb vibration, in linings of pipes or tanks conveying or holding acids or corrosive liquids, and where a positive fastening of rubber to adjoining metal parts is desired. Bonding may be effected by two processes. Large surfaces are cleaned and sand blasted and a vulcanizing cement applied. Uncured rubber sheets of the proper thickness then are laid on the metal and steam curing or vulcanizing effects the bond. Small molded parts are cleaned and electroplated with a suitable brass alloy. A special cement is applied, followed by the application of a piece of rubber of suitable size. The assembly is squeezed to shape in a mold in the presence of heat. The plating process can be applied to steel, nickel, zinc, aluminum, copper, brass, Monel metal and cast iron.

**EFFECT OF ORGANIC LIQUIDS AND VAPORS.**—In general, rubber is unaffected by weak acids, or weak caustic alkalies. Special hard rubber compounds are not attacked by concentrated hydrochloric or hydrofluoric acids, nor by sulphuric and nitric acids up to certain concentrations. Ozone cracks and soon destroys rubber, especially if it is under tension. Certain liquids and their vapors swell soft vulcanized rubber. The figures below show the absorption $Q$, in cu. cm. of liquid at room temperature, in one day by 1 cu. cm. of rubber. The values may be doubled or halved with different soft vulcanized rubber stocks. Special hard rubbers are only slightly, or not at all, affected by these liquids. In some cases the liquid will cause a slight softening of hard rubber.

| | $Q$ | | $Q$ | | $Q$ |
|---|---|---|---|---|---|
| Acetic acid | 0.1 | Carbon tetrachloride | 12.5 | Naphtha | 8.0 |
| Acetone | 0.2 | Castor oil | 0.01 | Nitrobenzine | 1.4 |
| Alcohol (ethyl) | 0.01 | Chloroform | 9.0 | Paraffin oil | 2.8 |
| " (methyl) | 0.02 | Cod liver oil | 1.3 | Petroleum | 6.0 |
| Aqueous ammonia | very small | Cottonseed oil (refined) | 1.0 | Rosin oil | 3.8 |
| Benzene | 5.8 | Creosote oil | 3.1 | Sperm oil | 1.8 |
| Benzyl chloride | 4.4 | Ethyl acetate | 0.4 | Tallow oil | 1.0 |
| Butter fat | 1.5 | Ethyl ether | 3.4 | Toluene | 7.4 |
| Butyric acid | very small | Gasoline | 4.0 | Turpentine | 5.5 |
| Carbon disulphide | 8.6 | Glycerine | 0.0 | Xylene | 6.3 |
| | | Linseed oil (raw) | 1.1 | | |

**DRIFT OF RUBBER.**—Rubber supporting a constant load over long periods undergoes a slowly increasing deformation called *drift*. Drift is distinguished from permanent set in that it is a measure of the deformation while the force is acting, not after the force is removed. Relative drift for $t$ days of constant load for a sandwich either in shear or compression is $(d_t - d_o)/d_o$, where $d_o$ = original deflection one minute after first application of load and $d_t$ = deflection $t$ days later. Relative drift depends, among other variables, on temperature, static load per unit area, operating media (oil and grease, which cause the rubber to deteriorate, appreciably change the drift), shape of rubber sample, etc. If the rubber sample is subjected to vibration, drift will be increased over that which would occur with purely static load.

**Shear Drift.**—The following are estimates of the approximate amount of drift to be expected under static loads causing 15% deflection in terms of sandwich thickness, after 24 hours constant loading at 100° F.:

| Stock No. | 5140 | 5488 | 5638 | 5255 | 5691 |
|---|---|---|---|---|---|
| Drift, percent | 2 | 5 | 8 | 12 | 15 |

After one year, these values of relative drift show a proportional increase, ranging from 20% for stock No. 5140 to 40% for stock No. 5691. That is, the deflection of stock No. 5140 used in shear to support a constant load corresponding to a 15% deflection will be, after one year, $15 \times \{1 + (20/100)\} = 18\%$.

**Compression Drift.**—Under static loads giving 15% initial compression, the relative drift after 24 hr. constant loading at 100° F. are approximately as follows:

| Stock No. | 5140 | 5488 | 5638 |
|---|---|---|---|
| Drift, percent | 2 | 4 | 8 |

The proportional increase after a period of one year ranges from 12% for No. 5140 stock to about 35% for No. 5638 stock. After two years, the relative drifts are 25% for No. 5140, 35% for No. 5488 and 50% for No. 5638. For rubber bushings, or rubber mountings, used under static loads and subject to continual vibration, stock No. 5140, from the standpoint of drift and vibration life, is better than the harder stocks.

## CARBON *

Essentially pure carbon occurs in widely varied forms from the diamond which is white, transparent and extremely hard, to graphite which is black, opaque and unctuous. Lampblack, charcoal and coke are practically pure carbon except for certain mineral or volatile impurities. Coal contains a very high percentage of carbon as well as a variety of tarry hydrocarbons from which the numerous coal tar products are derived. The peculiar physical and chemical characteristics of carbon adapt it to many uses for which no other material is available.

From a chemical standpoint carbon is very inactive, and resistant to most acids and other corrosive materials. It does not melt at incandescent temperatures, and the rate of oxidation is relatively slow. It can readily be formed in a variety of shapes during manufacturing operations, either in the initial plastic condition or by machining in solid form. In graphitic form, carbon is valuable as a lubricant where, because of temperature or other inhibiting factors, oil or grease lubrication is not feasible. The thermal conduc-

* The subscript indicates the number of zeros following the decimal point; thus $0.0_{4}21 = 0.000021$.

tivity of carbon, especially non-graphitic, is low as compared with most metals, but high as compared with most other solid materials. Carbon is a good conductor of electricity, but of much higher electrical resistance than the metals.

The applications of carbon include: Lighting carbons; carbon brushes for motors and generators; welding carbon products; carbon and graphite electrodes and anodes for electrochemical and electro-metallurgical industries; carbon Raschig rings, tubes, brick, tile and special structural shapes used in handling and processing acids and other corrosive materials; dry cells; switch and circuit breaker contacts; resistance discs; steam turbine packing; thrust rings for automobile clutches; back plates, diaphragms and granular carbon for telephones; anodes and grids for electronic devices; and, in the form of pure graphite powder, as a lubricant and a constituent of lubricating greases.

**PHYSICAL PROPERTIES.**—The physical properties of carbon in its various forms are given below.

**Specific Gravity** varies with the type of carbon and the method of manufacture as follows: Gas calcined coke carbon, 1.98–2.10 *; gas calcined lampblack carbon, 1.80–1.85 *; graphitized coke carbon, 2.20–2.24; graphitized lampblack carbon, 1.98–2.08; graphite, pure, 2.25; diamond, 3.51.

**Melting and Volatilization.**—Carbon volatilizes without melting at ordinary pressures, the volatilization point being 6629° F.

**Specific Heat** of various forms of carbon at various temperatures is given in Table 1.

**Coefficient of Thermal Expansion** of carbon in various forms is given in Table 2.

**Thermal Conductivity** of carbon in B.t.u. per hr. per sq. ft. per deg. F. per in. thickness, is as follows: Electrographitic brush, 68–108° F., 84.187; natural graphite brush, 68–108° F., 113.217; coke electrode, 68–108° F., 22.934; 108–644° F., 4.645; 644–1112° F., 3.484; graphitized electrodes, 68–108° F., 165.471; 108–644° F., 1190.23; 644–1112° F., 870.90.

**Electrical Resistivity** in ohms per cubic centimeter at 20° C. is: Carbon, coke base, 0.0035–0.0046; carbon, lampblack base, 0.0046–0.0056; graphite, 0.0008–0.0013.

**Strength** of carbon varies with the form as follows, values being given in pounds per square inch.

| | Tensile Strength | Crushing Strength | Transverse Strength |
|---|---|---|---|
| Carbon, coke base | 600–1250 | 2500–9000 | 1500–6000 |
| Graphite, artificial | 700–1200 | 3000–4000 | 3000–5000 |

**CARBON BRUSHES** are divided into six classes on the basis of composition, as follows:

**Carbon.**—Practically all amorphous carbon.

**Carbon-Graphite.**—Amorphous carbon with a small percentage of graphite.

**Graphite-Carbon.**—Amorphous carbon with a large percentage of graphite.

**Graphite.**—Practically all graphite.

**Electro-graphitic.**—Amorphous carbon, wholly or in part converted to graphite in the electric furnace.

**Metal-graphite.**—Various proportions of metal and graphite.

Because of the wide range of operating conditions encountered and the many conflicting demands of service, a great variety of brush grades are manufactured with a wide range of physical characteristics. For specific information on the application of various grades of brushes, the brush manufacturers should be consulted.

---

* Depends on source, character of bond, and degree of calcination.

**ELECTRODES.**—Carbon and graphite electrodes are important in the production of abrasives, aluminum, iron, steel, alloys, and carbide in the electric furnace, and in the electrolytic production of chlorine, caustic soda and other products. For the same physical size, graphite electrodes cost more than carbon electrodes but have lower electrical resistivity. For equivalent current-carrying capacity, graphite electrodes are much smaller than carbon electrodes.

Electrodes are made to specifications which vary somewhat with size, but, in general, are as follows: Permissible variation in diameter, ±2%; permissible curvature, $\frac{1}{2}$% of length, measured from the chord to arc of the electrode; minimum apparent density, carbon electrodes, 1.45, graphite electrodes, 1.51; electrodes must not show signs of coring or laminations, and surface must be clean and free from pits and blowholes.

Electrodes are made in many shapes and sizes. Round electrodes range from $\frac{1}{16}$ in. diam. and 12 in. long, to 18 in. diam. and 72 in. long for graphite, and up to 40 in. diam. and 110 in. long for carbon.

**Electrode Applications.**—Graphite electrodes are preferable to carbon for electrolytic operations. In electrothermic work, both carbon and graphite electrodes are used. Aluminum furnaces and carbide furnaces use carbon electrodes. Carbon electrodes are used for most ferroalloy furnaces with the exception of furnaces for ferrovanadium and some low-carbon steel alloys. Steel-making furnaces use both carbon and graphite electrodes, as do furnaces for making steel castings. Electric furnaces for gray iron castings use both carbon and graphite electrodes, the latter predominating. Furnaces for nonferrous materials use graphite electrodes almost exclusively. In the abrasive industry, both types are used, carbon electrodes predominating, although only graphite electrodes can be used for abrasives of very light color.

The principal factor governing choice of carbon or graphite electrodes is cost per ton of product. Where the electrodes are consumed slowly, as in the production of aluminum carbide and ferroalloys, carbon electrodes are preferred. Where the electrodes are consumed rapidly, as in iron and steel furnaces, graphite electrodes, which are but a little over half the size of the corresponding carbon electrodes for equivalent current-carrying capacity are preferable. The fact that in the steel and iron industry only about half as much graphite is used per ton of product offsets the higher cost of the carbon electrode. Graphite electrodes, because of their lighter weight for an equivalent current-carrying capacity, are more easily handled than carbon electrodes, control apparatus is more effective and the supporting structure can be made lighter. Further, the smaller size of the graphite electrode requires smaller ports in furnace walls and roofs with consequent less weakening of the structure. Many other factors enter into the correct choice of an electrode, and the manufacturer should be consulted in the selection of the electrode best suited to a given set of conditions. Table 3 gives current-carrying capacity of electrodes.

**Table 3.—Current-carrying Capacity of Carbon and Graphite Electrodes**
(National Carbon Co., Cleveland)

| Diam. or Side of Square, in. | Carbon Electrodes | | | | | Graphite Electrodes | | | | | |

**LIGHTING CARBONS.**—The original commercial application of carbon on an extensive scale was in the electric arc lamp. The principal types of carbons now made to meet specific applications of the carbon arc are motion picture projector carbons, motion picture studio carbons, photographic carbons, both white flame and panchromatic, searchlight carbons, enclosed arc carbons for blue printing, etc., therapeutic carbons, and industrial carbons. The three basic types of carbon arcs are the low-intensity neutral cored carbon arcs, the flame arc, and the high intensity arc. The intrinsic brilliancy of these types of carbon arcs in comparison with other light sources is given in Table 4.

**SPECTROSCOPIC CARBONS** are artificial graphite electrodes of exceptional purity used for spectroscopic analysis. The ash content is below 0.001%. This slight trace of impurity defies identification by chemical analysis, and in some cases is too small to produce visible lines in the spectrum other than those of the element carbon itself. In some cases, however, faint lines of other elements as Si, Mg, Ca, Fe, Al, Cu or Ag may be visible. Never are all of these impurities found in the same electrode and usually only one or two, and these in very minute quantity. Copper appears to be the most prevalent impurity. Spectroscopic electrodes are available in 6 in. and 12 in. lengths and in diameters $^3/_{16}$, $^1/_4$, $^5/_{16}$ and $^3/_8$ in.

**CHEMICAL CARBON PRODUCTS.**—Carbon is immune to reaction with most of the products encountered in chemical manufacturing plants at the concentrations and temperatures ordinarily employed. It is unaffected by all acids, alkalies, and salt solutions, except hot concentrated solutions of highly oxidizing character. Further, because of its high thermal conductivity and low coefficient of expansion, carbon is highly resistant to thermal shock. Carbon Raschig rings, tubes, bricks, tile and special structural shapes are the forms in which it is most extensively used in the chemical industries. Table 5 gives physical data on carbon Raschig rings.

**Carbon Bricks** are made in the same forms as standard refractory brick, but to slightly different dimensions. The approximate dimensions and weights per 100 brick of the

**Table 4.—Intrinsic Brilliancy of Light Sources**

(National Carbon Co., Cleveland)

| Light Source | Candle Power per sq. mm. |
|---|---|
| Magnetite arc stream | 6.2 |
| Flame arc stream | 8.0 |
| 900-watt, special tungsten filament, clear gas-filled bulb | 26.6 |
| Positive crater of cored D.C. low-intensity carbon arc | 155–175 |
| Crater of A.C. high-intensity carbon arc | 280 |
| Positive crater of non-rotating D.C. high-intensity carbon arc | 380 |
| Positive crater of rotating D.C. high-intensity carbon arc | 400–800 |
| Sun at zenith | 920–950 |

**WELDING CARBON PRODUCTS** include carbon and graphite welding electrodes, carbon rods, plates and paste. The latter are valuable aids in all classes of gas or electric welding operations. They are used for molds, cores and dams to restrict the flow of molten metal and to protect adjacent parts against excessive heating. They are of assistance in making vertical welds, in welding a break without dismantling the parts to be welded, in making forms for building up broken parts, and in supporting thin sections or light parts during welding.

In all arc welding, arc stability is an important factor, both as regards speed and the quality of the weld. In carbon arc welding this stability is best preserved by maintaining a small point approximately 1/8 in. diameter at the tip of the electrode. Most economical operation will be obtained when conditions are so adjusted that the combined effect of surface oxidation and reduction in length of electrode tends to form a taper from this small tip to the full diameter of the electrode in a length of 6 to 8 times the diameter. Factors affecting the form of the electrode tip are type of electrode, current density in electrode, distance from holder to tip of electrode, period of continuous operation, and method of cooling electrode. The operator should seek to establish conditions which will maintain the long tapered point described above. The exact current which will maintain this point cannot be specified, as it depends on many factors, but for average hand welding operations it probably will be within the following range:

| Electrode diam., in. | 1/8 | 3/16 | 1/4 | 5/16 | 3/8 | 7/16 | 1/2 | 5/8 | 3/4 | 7/8 | 1 |
|---|---|---|---|---|---|---|---|---|---|---|---|
| Welding current, amperes | | | | | | | | | | | |
| Max. | 0 | 25 | 50 | 80 | 110 | 140 | 170 | 230 | 290 | 350 | 400 |
| Min. | 35 | 60 | 90 | 125 | 165 | 210 | 260 | 370 | 490 | 615 | 750 |
| Max. current density, amperes per sq. in. | 2890 | 2200 | 1855 | 1650 | 1510 | 1420 | 1340 | 1220 | 1125 | 1035 | 965 |

# MISCELLANEOUS MATERIALS

**BRICKWORK.**—Brickwork is estimated by the thousand. The number of bricks for various thicknesses of wall is as follows:

| Thickness of wall, in. | 8 1/4 | 12 3/4 | 17 | 21 1/2 |
|---|---|---|---|---|
| Number of bricks thick | 1 | 1 1/2 | 2 | 2 1/2 |
| No. of bricks per superficial foot | 14 | 21 | 28 | 35 |

An ordinary brick is 8 1/4 × 4 × 2 in. = 66 cu. in. = 26.2 bricks per cu. ft. Its average weight is 4 1/2 lb.

**Clay and Sand-lime Brick.**—Table 1 gives the standard sizes of clay and sand-lime brick, and Table 2 the grades of brick according to strength. The compressive tests of Table 2 are made with a half-brick, flatwise, bedded in plaster-of-paris to provide an even bearing. The bending test is made with the brick flatwise, with the load applied at the middle of a 7-in. span. The average sand-lime brick is about equal in strength to a medium clay brick.

**Table 1.—Standard Sizes for Clay and Sand-lime Building Brick**

(A.S.T.M. Designations C62–30, C73–30)

| Types | Standard Sizes, in. | | | Permissible Variations, in. | | |
|---|---|---|---|---|---|---|
| | Depth | Width | Length | Depth | Width | Length |
| Common clay brick | 2 1/4 | 3 3/4 | 8 | ± 1/16 | ± 1/8 | ± 1/4 |
| Rough-face clay brick | 2 1/4 | 3 3/4 | 8 | ± 1/16 | ± 1/8 | ± 1/4 |
| Smooth-face clay brick | 2 1/4 | 3 7/8 | 8 | ± 1/16 | ± 1/8 | ± 1/4 |
| Sand-lime brick | 2 1/4 | 3 3/4 | 8 | ± 1/16 | ± 1/8 | ± 1/4 |

**Table 2.—Grades of Clay or Sand-lime Building Brick**

(A.S.T.M. Designations C62–30, C73–30)

| Name of Grade | Compressive Strength (bricks flatwise), lb. per sq. in., mean gross area | | Modulus of Rupture (bricks flatwise), lb. per sq. in., gross area | |
|---|---|---|---|---|
| | Mean of 5 tests | Individual minimum | Mean of 5 tests | Individual minimum |
| Grade A | 4500 or over | 3500 | 600 or over | 400 |
| Grade B | 2500–4500 | 2000 | 450 or over | 300 |
| Grade C | 1250–2500 | 1000 | 300 or over | 200 |

The above classifications are based on strength and do not necessarily measure weather resistance.

Chemical analysis throws light upon an important point in connection with asbestos, *i.e.*, the cause of the harshness of the fiber of some varieties. Asbestos is principally a hydrous silicate of magnesia, *i.e.*, silicate of magnesia combined with water. When harsh fiber is analyzed it is found to contain less water than the soft fiber. In fiber of very fine quality from Black Lake, analysis showed 14.38% of water, while a harsh-fibered sample gave only 11.70%. If soft fiber be heated to a temperature that will drive off a portion of the combined water, there results a substance so brittle that it may be crumbled between thumb and finger. There is evidently a connection between the consistency of the fiber and the amount of water in its composition.

**Asbestos Yarns** are numbered according to the number of yards per pound. Thus No. 1 yarn contains 100 yd. per lb.; No. 2 yarn, 200 yd. per lb.; No. 10 yarn, 1000 yd. per lb., etc. In multi-ply yarns, the yardage multiplied by the number of plies gives the yarn number. A three-ply yarn, of 600 lb. per yd., is equivalent to 600 × 3 = 1800 yd. of single-ply No. 18 yarn, and is known as three-ply, No. 18.

**CEMENT.**—Weighs from 90 to 118 lb. per cu. ft. The following are the legal commercial measures:

| | Net Wt. per Barrel, lb. | Net Wt. per Bag, lb. |
|---|---|---|
| Portland cement | 376 | 94 |
| Natural cement | 282 | 94 |

**ZIRCONIA.**—Zirconia ore (84.1 $ZrO_2$; 7.74 $SiO_2$; 3.10 $Fe_2O_3$; 1.21 $TiO_2$; 0.06 $Al_2O_3$; loss on ignition 2.72) vitrifies slightly at 1830° C. (3326° F.). Mixed with different percentages of clay and molded into cones it vitrifies at somewhat lower temperatures. A zirconia brick containing 5% clay became plastic on its face at 1800° C. (3272° F.). (H. Conrad Meyer, *Met. & Chem. Engg.*, vol. xii, No. 12, 1914; vol. xiii, No. 4, 1915; Circular of Foote Mineral Co., Philadelphia.)

## PLATES, SHEETS, BARS, RODS AND SHAPES

**FORMULAS FOR WEIGHT OF PLATE STEEL.**—Based on a unit weight of steel of 0.284 lb. per cu. in., the weight of plate steel, either rectangular or circular, can be found by the formulas

$$\text{Rectangular plate, } W = B \times L \times C; \text{ Circular plate, } W = D \times K$$

where $W$ = weight, lb.; $B$ = width of plate, in.; $L$ = length of plate, in.; $D$ = diameter of plate, in.; $C$ and $K$ = constants whose values are given in Table 1.

**Table 1.—Values of $C$ and $K$**

$T$ = thickness of plate, in.

| $T =$ | 3/16 | 1/4 | 5/16 | 3/8 | 7/16 | 1/2 | 9/16 | 5/8 | 3/4 | 7/8 | 1 |
|---|---|---|---|---|---|---|---|---|---|---|---|
| $C =$ | 0.0533 | 0.0710 | 0.0888 | 0.1065 | 0.1243 | 0.142 | 0.160 | 0.178 | 0.215 | 0.2485 | 0.284 |
| $K =$ | 0.0419 | 0.0558 | 0.0697 | 0.0839 | 0.0965 | 0.1122 | 0.1255 | 0.1394 | 0.1673 | 0.1952 | 0.2238 |

**WEIGHT OF COMMERCIAL PLATE AND SHEET.**—Table 3 gives the weight of plate iron, in thicknesses up to 1 in. Table 3 can be used for steel, by adding 2% to the values given for iron. Table 4 gives the weight of rectangular sections of steel, and Table 5 the cross-sectional areas of the sections given in Table 4.

**Non-ferrous Sheet and Plate.**—Tables 6 to 10 and 14 give the weight of plate and sheet of brass and zinc. Approximate weights of plate and sheet of other metals can be found by the application of the data in Table 2. For data on aluminum plates, see p. 6–08.

**BARS, RODS AND SHAPES.**—Table 2 gives constants by which the weight of bars, rods, plates, tubes and spheres of various materials can be calculated. The table is based on the following formulas:

**Notation.**—$b$ = breadth; $t$ = thickness; $s$ = side of square; $D$ = external diameter; $d$ = internal diameter, all in inches. $v$ = volume of 1 ft. length, cu. in., $w$ = weight, lb. per cu. in.

**Square Bars.**—Sectional area = $s^2$; volume of 1 ft. length = $v = 12s^2$; weight = $w \times v$.

**Round Bars.**—Sectional area = $0.7854\ D^2$; volume of 1 ft. length = $v = 9.4248\ D^2$; weight of 1 foot length = $w \times v = w \times 9.4248\ D^2$.

**Flats.**—Sectional area = $bt$; volume of 1 ft. length = $v = 12bt$; weight of 1 ft. length = $wv = 12\ wbt$.

**Tubes.**—Sectional area = $0.7854\ (D^2 - d^2) = 3.1416\ (Dt - t^2)$; volume of 1 ft.

(*Continued on p. 6–08*)

**Table 2.—Weight of Rods, Bars, Plates, Tubes and Spheres of Various Materials**

| Material | Specific Gravity | Weight per cu. ft., lb. | Weight of Plates 1 in. Thick, per sq. ft., lb. | Weight per ft. of Square Bars, lb. | Weight per ft. of Flat Bars, lb. | Weight per cu. in., lb. | Relative Weight. Wrought Iron = 1 | Weight per ft. of Round Rod, lb. | Weight of Spheres, lb. |
|---|---|---|---|---|---|---|---|---|---|
| | | | | $s^2 \times$ | $bt \times$ | | | $D^2 \times$ | $D^3 \times$ |
| Cast iron | 7.218 | 450. | 37.5 | 3 1/8 | 3 1/8 | 0.2604 | 15/16 | 2.454 | 0.1363 |
| Wrought iron | 7.7 | 480. | 40. | 3 1/3 | 3 1/3 | .2779 | 1. | 2.618 | .1455 |

By combining various widths given, the weight of any size piece can be determined.

*Density of brass = 0.306 lb. per cu. in. To obtain the weight of sheet copper multiply the figures in the table by 1.0508.

*(Continued from p. 6–03.)*

length = $v = 9.4248\ (D^2 - d^2) = 37.699\ (Dt - t^2)$; weight of 1 ft. length = $wv = 9.4248\ w(D^2 - d^2) = 37.699\ w(Dt - t^2)$. In using Table 2 for tubes, multiply the coefficient for round rods by $(D^2 - d^2)$ or by $4(Dt - t^2)$.

**Spheres.**—Weight of sphere = $0.5236\ wD^3$; for hollow spheres multiply the coefficient for spheres in Table 2 by $(D^3 - d^3)$.

**Hexagons.**—To find weight of hexagonal bar multiply the weight of square bars by 0.866 (short diameter of hexagon = side of square).

**Octagons.**—To find weight of octagonal bar, multiply the weight of square bar by 0.8284 (short diameter of octagon = side of square).

**COMMERCIAL RODS AND BARS.**—Tables 15 and 16 give the weights and areas of commercial square, round and hexagonal steel bars. Tables 11, 17, 18 and 19 give the weights of non-ferrous rods and bars.

* $I$ = moment of inertia; $S$ = section modulus; $r$ = radius of gyration; $x$, $y$ = distance from extreme fiber to neutral axis.

# STEEL, COPPER AND OTHER WIRES

Table 1 was calculated on the basis of 483.84 lb. per cu. ft. for steel wire. Iron wire is a trifle lighter.

The breaking strengths are calculated for 100,000 lb. per sq. in. throughout simply for convenience, so that the breaking strength of wires of any strength per square inch may be quickly determined by multiplying the values given in the tables by the ratio between strength per square inch and 100,000; thus a No. 15 wire with a strength per square inch of 150,000 lb. has a breaking strength of:

$$407 \times 150{,}000/100{,}000 = 610.5 \text{ lb. per sq. in.}$$

## 1. PLOW STEEL WIRE

The term "Plow" was given in England to steel wire of high quality which was used in connection with the construction of wire ropes used for plowing purposes. The term has become inseparably linked with a high-grade wire rope, lists of which will be found under Wire Rope, p. 6-34. It should not be confused with the quality of plate steel used for mold-boards of plows, for which a very ordinary grade is good enough.

The practice of various manufacturers differs somewhat, but ordinarily plow steel is a high-grade open-hearth steel, ranging in carbon from 0.50 to 0.95, depending on the diameter of finished wire. The lower carbon is used in the smaller, and the higher in the larger wire. Phosphorus and sulphur are 0.050 or under; manganese and silicon in varying quantities.

It has been the custom in the industry to classify the different grades of wire according to tensile strength in pounds per square inch throughout the general commercial range of wire sizes. Plow steel falls within the limits of 224,000 to 246,000 lb. per sq. in., with the lower strengths applying to the coarser sizes and the higher strengths to the finer sizes. This wire is used largely for wire ropes, springs, and similar purposes.

## 2. CAST STEEL WIRE

The term cast steel applied to a steel used in rope manufacture indicates, in general, a composition as follows: Carbon, 0.40 to 0.70; phosphorus and sulphur, 0.040 and under; manganese and silicon, in varying quantities. Cast steel wire invariably is made in the open-hearth furnace and is of lower tensile strength than plow steel. It has been the custom in the industry to classify the different grades of wire according to the tensile strength in pounds per square inch throughout the general commercial range of wire sizes. Cast steel falls within the limits of 179,200 to 201,600 lb. per sq. in., with the lower strengths applying to the coarser sizes and the higher strengths to the finer sizes. This wire is used largely for wire rope, springs, and similar purposes.

## 3. WIRE FOR TELEGRAPH AND TELEPHONE LINES

SIZES OF GALVANIZED IRON WIRE USED IN TELEGRAPH AND TELEPHONE LINES.—No. 4. Has not been much used until recently; is now used on important lines where the multiplex systems are applied.

No. 6. Used for important circuits between cities.

No. 8. Medium size for circuits of 400 miles or less.

No. 9. For similar locations to No. 8, but on somewhat shorter circuits; until recently was the size most largely used in this country.

Nos. 10, 11. For shorter circuits, railway telegraphs, private lines, police and fire-alarm lines, etc.

No. 12. For telephone lines, police and fire-alarm lines, etc.

No. 14. For telephone lines and short private lines; steel wire is used most generally in these sizes.

The coating of telegraph wire with zinc as a protection against oxidation is now generally admitted to be the most efficacious method.

The grades of line wire are generally known to the trade as "Extra Best Best" (E. B. B.), "Best Best" (B. B.), and "Steel."

**JOINTS IN TELEGRAPH WIRES.**—The fewer the joints in a line the better. All joints should be carefully made and well soldered over, for a bad joint may cause as much resistance to the electric current as several miles of wire.

**Table 1.—Properties of Steel Wire**

(John A. Roebling's Sons. Co., Trenton, N. J.)

**SPECIFICATIONS.**—(Abstracted from the standard specifications of the American Steel and Wire Co., and John A. Roebling's Sons Co.)—The scope of the specifications cover the usual requirements of the grades E. B. B., B. B. and Steel.

*Finish.*—The rods, before drawing must not contain any joint, weld or splice. The galvanizing shall consist of a continuous coating of pure zinc, of uniform thickness, so applied that it adheres firmly and presents a smooth surface.

Electrical and Physical Requirements

| Grade | Permissible Variation in Mile-ohm-pound Constant See Note 1 | Average Tensile Strength, lb. per sq. in. | Constant for Minimum Actual Breaking Weight See Note 2 |
|---|---|---|---|
| E.B.B. ........ | 4700–5000 | 45,500 | 2.5 |
| B.B. .......... | 5600–6000 | 51,000 | 2.8 |
| Steel .......... | 6500–7000 | 54,500 | 3.0 |

**Note 1.**—Mile-ohm-pound constant = actual resistance per mile at 68° F. × actual weight, lb. per mile.

**Note 2.**—Actual breaking weight = weight per mile × constant in table.

**Variation in Diameter.**—Permissible variations in diameter are as follows: Sizes, 4 to 11, inclusive, B. W. G., variation 0.004 in. either way; sizes 12 to 14 inclusive, B. W. G., variation 0.003 in. either way.

**Galvanizing Test.**—Samples, after cleaning by gasoline and cotton waste, rinsing in clean water and wiped dry with clean cotton waste, shall be immersed in the solution to a depth of 4 in. Samples shall be so separated that the solution may act uniformly on all immersed portions. The solution shall be a solution of commercial copper sulphate, specific gravity 1.186 at 65° F., neutralized by the addition of an excess of chemically pure cupric oxide (CuO) which shall collect in the bottom of the containing vessel. Solution is to be filtered before use. Not less than 4 oz. of fresh solution is to be used for each test of 7 wires, and it must be maintained at a temperature between 62° F. and 68° F. during the test. Four immersions of 1 minute each shall be given the samples, which are to be washed in clear water of between 62° F. and 68° F. between each immersion and then wiped dry with cotton waste. On sizes Nos. 13 and 14 B. W. G., the fourth immersion shall be of $1/2$ minute duration. A bright copper deposit after the fourth immersion indicates that the wire represented by the samples is faulty. Copper deposited on zinc, or within 1 inch of the end of a sample, shall not be considered cause for rejection.

**Coils and Splices.**—All wire shall be furnished in coils, whose usual inside diameter is 21 $1/2$ in. The approximate length of wire in each coil shall be:

Nos. 4 and 5, $1/4$ mile; Nos. 6 and 7, $1/3$ mile; No. 8 and smaller, $1/2$ mile. One-half the coils of No. 10 wire, and smaller, and each coil of No. 10 and larger may contain one splice. The splice may be made by electrical welding or by the ordinary twist joint thoroughly galvanized. In handling this wire the greatest care should be observed to avoid kinks, bends, scratches or cuts. Joints should be made only with McIntire connectors.

**SELECTION OF WIRE.**—On account of its conductivity being about five times that of E. B. B. steel wire, and its breaking strength over three times its weight per mile, copper may be used of which the section is smaller and the weight less than an equivalent steel wire, allowing a greater number of wires to be strung on the poles. Besides this advantage, the reduction of section materially decreases the electrostatic capacity, while its non-magnetic character lessens the self-induction of the line, both of which features tend to increase the possible speed of signaling in telegraphing, and to give greater clearness of enunciation over telephone lines, especially those of great length.

Steel is not economical as a transmission line material, except where a copper wire considerably larger than necessary is required to support, theoretically, an ice load. The product of the mile-ohm and the price per pound of wires gives a measure of their relative cost, taking into consideration their efficiency as conductors.

Telephone wires may be either hard-drawn copper or galvanized steel. The copper runs from 165 to 64 mils, and the steel from 283 to 83 mils. The ground wire carried on top of the poles is usually a 3/8-in. galvanized Siemens-Martin strand.

## 4. NON-FERROUS WIRE

**SILICON-BRONZE WIRE** has a conductivity of from 40 to 98% that of copper wire, and about 4 times that of iron wire. Its tensile strength is nearly that of steel or 28 to 55 tons per sq. in. of section. The conductivity decreases as the tensile strength increases. Wire whose conductivity equals 95% of that of pure copper gives a tensile strength of 28 tons per sq. in., but when its conductivity is 34% that of pure copper, its strength is 50 tons per sq. in. It is largely used for telegraph wires and has great resistance to oxidation.

**Table 4.—Properties of Bronze Wire, 68° F.**

(John A. Roebling's Sons Co., Trenton, N. J.)

## 5. WIRE GAGES AND SHEET METAL GAGES

The two wire gages in most extensive use in the United States are the American Wire Gage, also known as the Brown & Sharpe Gage, and the United States Steel Wire Gage more commonly called simply Steel Wire Gage.

Three other wire gages have remained in use but are now almost obsolete. These are the Birmingham Wire Gage, the Stubs Steel Wire Gage and the Old English Wire Gage. There are also certain special gages, as the drill and screw rod gages and the music wire gage. The one most frequently used is the Birmingham Gage sometimes called the Stubs Wire Gage. Its use in this country has been practically limited to large telegraph and telephone companies and certain departments of the Government. It is used by the Treasury Department for use in the collection of duties on imports of wire.

As there are many gages in use differing from each other, and even the thicknesses of a certain specified gage, as the Birmingham, are not assumed the same by all manufacturers, orders for sheets and wires should always state the weight per square foot, or the thickness in thousandths of an inch.

**THE AMERICAN WIRE GAGE** (Brown & Sharpe Gage) is practically the only gage used for copper and aluminum wire and, in general, for all wire used in electrical work. Sizes of stranded conductors larger than No. 0000 A.W.G. are specified by the cross-section in circular mils. The American Wire Gage also is used for sheets of copper, aluminum and other non-ferrous metals.

* See also Table 14.

**THE STEEL WIRE GAGE** is the same gage which formerly was known by the names of Washburn & Moen Gage and the American Steel & Wire Co. Gage. This gage, with certain of its sizes rounded off to even thousandths of an inch, is identical with the Roebling Gage. It is used for practically all steel wire in the United States.

While the two gages above are practically standard and have received official although not legal sanction, the trend of practice is toward the specifying of all sizes of wire and sheet material in decimals of an inch rather than by gage numbers.

**STUBS STEEL WIRE GAGE** has a somewhat limited use for tool steel wire and drill rods. It should not be confused with the Birmingham Wire Gage which is sometimes known as Stubs Iron Wire Gage.

**THE STANDARD WIRE GAGE** also known as the New British Standard, the English Legal Standard, or the Imperial Wire Gage is the legal standard of Great Britain for all wires. It was constructed by so modifying the Birmingham Wire Gage that the differences between successive diameters were the same for short lengths.

**MUSIC WIRE GAGE.**—Several gages are in use for music wire. Two of the most extensively used are given in Table 12. For data on others, see *Machinery's Handbook.*

**THE EDISON OR CIRCULAR MIL WIRE GAGE.**—The basis of the graduation is the sectional area, and the number of the wire corresponds. A wire of 100,000 circular mils area is No. 100; a wire of one-half the size will be No. 50; twice the size No. 200. With this gage, the number increases with the wire, and the number multiplied by 1000 will give the circular mils. The weight per mil-foot of copper wire, 0.000 003 027 05 pound, agrees with a specific gravity of 8.889. The ampere capacity which is given was deduced from experiments made in the Edison company's laboratory, and is based on a rise of temperature of 50° F. in the wire.

**The U. S. STANDARD GAGE FOR SHEET AND PLATE IRON AND STEEL.**—An Act of Congress in 1893 established the Standard Gage for sheet iron and steel. It is based on the fact that a cubic foot of iron weighs 480 pounds.

A sheet of iron 1 ft. square and 1 in. thick weighs 40 lb., or 640 oz., and 1 oz. in weight should be $^1/_{640}$ in. thick. The scale has been arranged so that each descriptive number

| Q | .332 | G | .261 | | | 60 | .039 | 70 | .027 | 80 | .013 |

represents a certain number of ounces in weight and an equal number of 640ths of an inch in thickness.

The law enacts that on and after July 1, 1893, the new gage shall be used in determining duties and taxes levied on sheet and plate iron and steel; and that in its application a variation of 2 1/2% either way may be allowed.

The U. S. Standard Gage for Sheet and Plate Iron is a *weight* gage, not a thickness gage, and is based on the following assumptions:

| | Iron | Steel |
|---|---|---|
| Specific gravity | 7.7 | 7.854 |
| Weight per cubic foot | 480. | 489.6 |
| Weight per cubic inch | 0.2778 | 0.2833 |

It applies to iron only, and for steel the thickness would vary as 480/489.6.

* Four strand rope weighs about 5% more than 3-strand rope; the tensile strength is about the same as that of 3-strand rope.

**STRESS DUE TO LENGTH OF VERTICAL ROPE.**—In a very long rope the weight of the rope itself adds a considerable amount to the stress in the rope, and decreases the load that the rope can safely carry. The weight of the rope, as a whole, can be diminished by making it up of a series of ropes of constantly decreasing diameters, the smallest rope being at the lower end. Table 2 shows the length of rope, hanging vertical, that will develop the maximum stress in the rope. The figures are based on the values of Table 1.

**Table 2.—Length of Vertical Rope Required to Develop Maximum Stress**

| Circumference, in. | Length in feet to Develop Maximum Stress | | Circumference, in. | Length in feet to Develop Maximum Stress | | Circumference, in. | Length in feet to Develop Maximum Stress | |
|---|---|---|---|---|---|---|---|---|
| | Breaking | Working | | Breaking | Working | | Breaking | Working |

| 3 | 3315 | 663 | 6 | 2870 | 574 | 12 | 2410 | 482 |

**MANILA ROPE FOR HOISTING OR TRANSMISSION.**—Rope for hoisting or power transmission is subject to severe usage. Ordinary rope chafes and grinds to powder in the center, while the exterior may look as though it was little worn. In bending a rope over a sheave, the strands and the yarns of these strands slide a small distance upon each other, causing friction, and wearing the rope internally. This condition can be alleviated by proper lubrication of the rope. The selection of the lubricant depends on the use of the rope. For indoor use, the lubricant should be one that will not dry out the rope, nor rub off easily. For outdoor use, a graphite lubricant of fine flake graphite should be worked into the yarns while the rope is being made, so that each fiber is impregnated.

In manufacturing rope, the fibers are first spun into a yarn, this yarn being twisted in a direction called "right hand." From 20 to 80 of these yarns, depending on the size of the rope, then are put together and twisted in the opposite direction, or "left hand," into a strand. Three of these strands, for a 3-strand, or four for a 4-strand rope, are then twisted together, the twist being again in the "right hand" direction. When the strand is twisted, it untwists each of the threads, and when the three strands are twisted together into rope, it untwists the strands, but again twists up the threads. It is this opposite twist that keeps the rope in its proper form. A weight hung on the end of a rope tends to untwist the rope, and make it longer. In untwisting, the threads twist up, and the weight will revolve until the strain of the untwisting strands just equals the strain of the threads being twisted tighter. In making a rope it is impossible to make these strains exactly balance each other. It is this fact that makes it necessary to take out the "turns" in a new rope, that is, untwist it when it is put to work. The proper twist that should be put in the threads has been ascertained approximately by experience.

The amount of work that the rope will do varies greatly. It depends not only on the quality of the fiber and the method of laying up the rope, but also on weather when the rope is used, the blocks or sheaves over which it is run, and the strain in proportion to the strain put upon the rope. The principal wear comes in practice from defective or badly set sheaves, from excess of load and exposure to storms.

Loads put on the rope should not exceed those given in the tables, for the most economical wear. Indications of excessive load will be the twist coming out of the rope, or one of the strands slipping out of its proper position. A certain amount of twist comes out in use in the first day or two, but the rope then should remain substantially the same. If it does not, the load is too great for the durability of the rope. Wear of the rope on the outside, while it is good on the inside, indicates chafing in running over pulleys or sheaves. If the blocks are very small, it will increase the sliding of the strands and threads, and result in a more rapid internal wear. For further information on rope for power transmission, see p. 24–48.

**TECHNICAL TERMS RELATING TO CORDAGE** most frequently used are:

**Yarn.**—Fibers twisted together. Yarns are laid up left-handed into *strands.*

**Thread.**—Two or more *small yarns* twisted together.

**String.**—The same as a thread but of a little larger *yarns.*

**Strand.**—Two or more *large yarns* twisted together. Strands are laid up right-handed into rope.

**Cord.**—Several threads twisted together.

**Rope.**—Several *strands* twisted together.

**Hawser.**—A rope of three *strands.* Hawsers are laid up left-handed into a cable.

**Shroud-laid.**—A rope of four *strands.*

**Cable.**—Three hawsers twisted together.

A rope is:

**Laid** by twisting strands together in making the rope.

**Spliced** by joining to another rope by interweaving the strands.

**Whipped.**—By winding a string around the end to prevent untwisting.

**Served.**—When covered by winding a yarn continuously and tightly around it.

**Parceled.**—By wrapping with canvas.

**Seized.**—When two parts are bound together by a yarn, thread or string.

**Payed.**—When painted, tarred or greased to resist wet.

**Haul.**—To pull on a rope.

**Taut.**—Drawn tight or strained.

SPLICING OF ROPE.—The splice in a transmission rope is not only the weakest part of the rope but is the first part to fail when the rope is worn out. If the rope is larger at the splice, the projecting part will wear on the pulleys and the rope fail from the cutting off of the strands. The following directions are given for splicing a 4-strand rope:

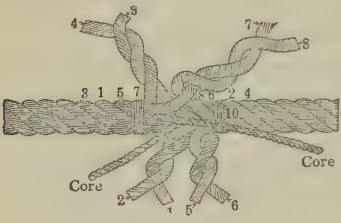

FIG. 1

Tie a piece of twine, 9 and 10, around the rope to be spliced, about 6 ft. from each end, and unlay the strands of each end back to the twine. Butt the ropes together and twist each corresponding pair of strands loosely to prevent them being tangled. (See Fig. 1.) The twine 10 is now cut, and the strand 8 unlaid and strand 7 carefully laid in its place for a distance of 4 1/2 ft. from the junction. The strand 6 is next unlaid about 1 1/2 ft. and strand 5 laid in its place. The ends of the cores are now cut off so they just meet. Unlay strand 1 a distance of 4 1/2 ft., laying strand 2 in its place. Unlay strand 3 about 1 1/2 ft., laying in strand 4.

Cut all the strands off to a length of about 20 in. for convenience in manipulation. The rope now assumes the form shown in Fig. 2 with the meeting points of the strands three feet apart.

Each pair of strands is successively subjected to the following operation:

From the point of meeting of the strands 8 and 7, unlay each one three turns; split both the strand 8 and the strand 7 in halves as far back as they are now unlaid and "whip" the end of each half strand with a small piece of twine.

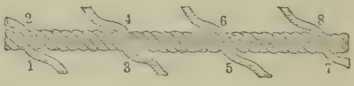

FIG. 2

The half of the strand 7 is now laid in three turns and the half of 8 also laid in three turns. The half strands now meet and are tied in a simple knot, 11, Fig. 3, making the rope at this point its original size.

The rope is now opened with a marlin spike and the half strand of 7 worked around the half strand of 8 by passing the end of the half strand 7 through the rope, as shown, drawn taut, and again worked around this half strand until it reaches the half strand 13 that was not laid in. This half strand 13 is now split, and the half strand 7 drawn through the opening thus made, and then tucked under the two adjacent strands, as shown in Fig. 4. The other half of the strand 8 is now wound around the other half strand 7 in the same manner. After each pair of strands has been treated in this manner, the ends are cut off at 12, leaving them about 4 in. long. After a few days wear they will draw into the body of the rope or wear off.

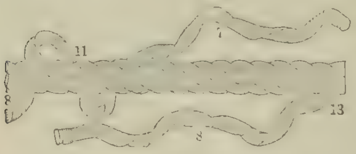

FIG. 3

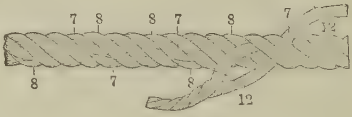

FIG. 4

KNOTS.—The principle of a knot is that no two parts, which would move in the same direction if the rope were to slip, should lay alongside of and touching each other. (See Fig. 5.)

The Bowline is one of the most useful knots; it will not slip, and after being stressed is easily untied. Commence by making a bight in the rope; then put the end through the bight and under the standing part as shown in *G*; then pass the end again through the bight, and haul tight.

The Square or Reef Knot must not be mistaken for the "granny" knot that slips under a stress. Knots *H*, *K*, and *M* are easily untied after being under stress. The knot *M* is useful when the rope passes through an eye and is held by the knot, as it will not slip and is easily untied after being stressed.

The timber hitch *S* looks as though it would give way, but it will not; the greater the stress the tighter it will hold. The wall knot looks complicated, but is easily made by proceeding as follows: Form a bight with strand 1 and pass strand 2 around the end of it, and strand 3 around the end of 2 and then through the bight of 1 as shown at *Z*. Haul the ends taut; the appearance is as shown at *AA*. The end of the strand 1 is now laid over the center of the knot, strand 2 laid over 1, and strand 3 over 2; the end of 3 is passed through the bight of 1 as shown at *BB*. Haul all the strands taut as shown at *CC*.

**Varieties of Knots.**—A great number of knots have been devised of which a few only are illustrated; those selected are the most frequently used. In Fig. 5, they are shown before being drawn taut, in order to show the position of the parts. The names usually given to them are:

A. Bight of a rope.
B. Simple or overhand knot.
C. Figure 8 knot.
D. Double knot.
E. Boat knot.
F. Bowline, first step.
G. Bowline, second step.
H. Bowline completed.
I. Square or reef knot.
J. Sheet bend or weaver's knot.
K. Sheet bend with a toggle.
L. Carrick bend.
M. Stevedore knot completed.
N. Stevedore knot commenced.
O. Slip knot.
P. Flemish loop.
Q. Chain knot with toggle.
R. Half-hitch.
S. Timber-hitch.
T. Clove-hitch.
U. Rolling-hitch.
V. Timber-hitch and half-hitch.
W. Blackwall-hitch.
X. Fisherman's bend.
Y. Round turn and half-hitch.
Z. Wall knot commenced.
AA. Wall knot completed.
BB. Wall knot crown commenced.
CC. Wall knot crown completed.

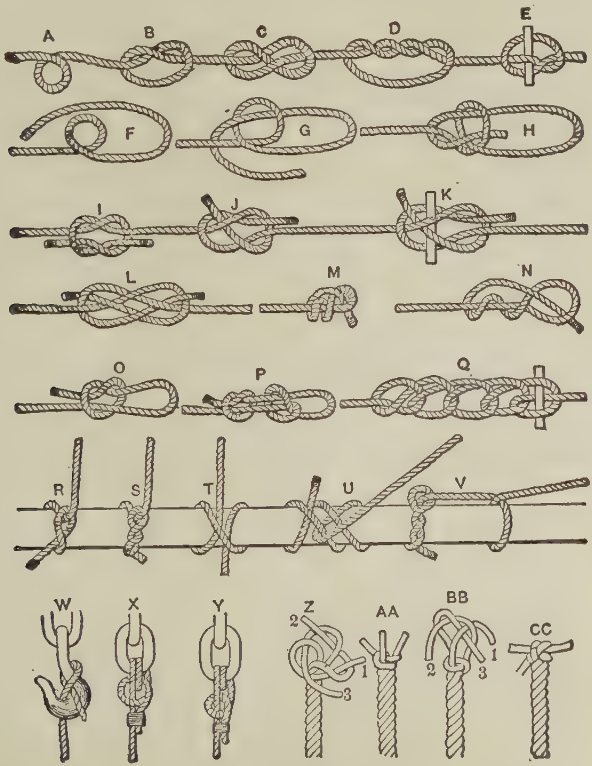

Fig. 5. Varieties of Knots

**EFFICIENCY OF KNOTS** as a percentage of the full strength of the rope, and the factor of safety when used with the stresses given below are as follows:

| Kind of Knot. | Efficiency, % | Factor of Safety |
|---|---|---|
| Eye splice over an iron thimble | 90 | 6.3 |
| Short splice in the rope | 80 | 5.6 |
| Timber hitch, round turn, half-hitch | 65 | 4.5 |
| Bowline slip knot, clove hitch | 60 | 4.2 |
| Square knot, weaver's knot, sheet bend | 50 | 3.5 |
| Flemish loop, overhand knot | 45 | 3.1 |
| Full strength of dry rope, average of four tests | 100 | 7.0 |

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| Diameter of rope, in. | 1 | 1 1/8 | 1 1/4 | 1 3/8 | 1 1/2 | 1 5/8 | 1 3/4 |
| Working stress, lb. | 1000 | 1250 | 1500 | 1900 | 2200 | 2600 | 3000 |

## 2. CHAINS

**CLASSES OF CHAIN.**—**Crane Chain**, for slings, hoists, steam shovels, and marine uses, and where an all-iron chain is desired.

**Proof Coil**, for railroad cars, construction and forestry work.

The A.S.T.M. standard specifications (A56–30) for iron and steel chain provide:

**Crane Chain** shall be made from wrought iron free from any admixture of iron scrap or steel, and lap fire welded.

**Proof Coil** may be made from open-hearth steel or all reworked steel and iron scrap. It may be made by fire- or electric welding. Chemical requirements are: Wrought-iron crane chain, Mn (max.), 0.10% steel proof coil, P (max.), 0.05%, S (max.), 0.05%.

**Physical Properties and Tests.**—All chain shall be subjected to the proof test load, shown in Table 3 for the respective size chain, without showing any defects. Test specimens, of not less than 2 ft., cut from the finished chain, shall conform to the minimum requirements for the break test loads specified in Table 4. The elongation, determined in a gage length of from 12 to 18 in. to the nearest link, shall not be less than 15% for both crane and proof coil chain.

**Standard Weights and Dimensions.**—The nominal length of 100 links, the nominal weight per 100 ft., and the nominal dimensions of links are specified in Table 4, with a permissible variation for length and weight of chain of ± 4%. The length is determined by measuring to the inside of the end links, and after the proof test, and with a load not exceeding 10% of the proof test load specified in Table 3 to take up slack. The diameter of the bar in all chain is not to be less than the nominal size in the body and welds. The diameter of the weld shall not exceed the diameter of the bar by more than 25%.

**CAUSES OF CHAIN FAILURE.**—**1. Brittle Failure** caused by cold-working of the metal surface. The metal fractures with no elongation, or with less elongation than in the ordinary tensile failure mentioned under (6). This type of fracture usually is caused by a brittle surface skin developed on the metal by impacts received in service. Brittle

failures show a more or less crystalline fracture, especially where the brittleness is present in an extreme degree. In service, fractures caused by cold-working the surface occur most frequently in the sides or near the shoulder of the link. Where the surface hardening is extreme, the fracture extends directly across the metal of the link in an approximately plane surface. Brittle failures usually are found in chain which has failed under the impact of suddenly-applied loads.

**2. Failure in the Weld** covers any failure involving partial or total separation of the welded surfaces. In old chain, welded surfaces often show signs of progressive deterioration and oxidation.

**3. Failure Due to Repeated Severe Bending or Deformation of the Links** is similar to that produced in a bar by repeated bending back and forth. This is common in long-link chains, as conveyor chains. The fractured surface usually is crystalline both in wrought iron and steel.

**4. Fatigue Failure** produced by many repetitions of stress exceeding the fatigue limit of the metal. In fatigue tests on chain links, the fracture usually occurs at about the quarter point of the link. The fracture extends directly across the side of the link. Fatigue failure occurs in chain in machines or appliances used for repeated liftings of a given load, but is not common in crane chains and sling chains. There is no elongation of the metal. The fractured surface is usually plane and crystalline.

**5. Brittle Failure Caused by Defects in the Metal.**—Occasional types of brittle fracture are caused by defects in the original iron or steel. Such failures are comparatively rare. The proof test by the manufacturer detects brittleness from this cause, and the links are removed. Brittle fractures, due to overheating during welding, are rare.

**6. Ordinary Tensile Failure,** accompanied by full elongation of the metal of the links, usually occurs in new chain of good quality when the chain is required to carry a load greater than its ultimate tensile strength. The metal of the links elongates greatly and the chain "pulls stiff" before final failure. The fracture usually occurs in the sides of the links near the welded end. The metal "necks down" and pulls apart as in an ordinary tension test. The fractured surfaces are generally silky in the case of steel, or fibrous in the case of wrought iron.

**USE OF CHAIN.**—The diameter of a sheave or winding drum used with a short link chain should be from 25 to 30 times the diameter of the stock used for the link, to minimize the bending stresses in the chain as it passes over the sheave or drum. Where the application requires a longer link the chain manufacturer should be consulted as to the proper size of drum or sheave. Sheaves and drums used should be grooved to receive the chain. These grooves should be of such shape and size as to allow the chain to work smoothly without twisting. Chain should not be wound on sheaves, shafts, or drums without proper grooves.

**Splicing of Broken Chain.**—A dangerous practice, which should be prohibited, is that

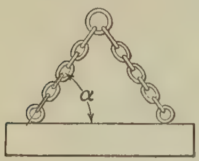

Fig 6. Sling Chain Angles

of splicing a broken chain by inserting a bolt between two links, with the head of the bolt and the nut sustaining the load, or of passing one link through another and inserting a bolt or nail to hold it.

**Kinked, Knotted, or Twisted Chain.**—A lift never should be made with a kink, knot, or twist in the chain. The chain should be perfectly straight. Twisting and dragging chain over pipe and other materials injures the chain.

**Safe Loads.**—Some plants stamp on a metal tag attached to each chain the safe vertical load which may be lifted with that chain. A better way is to stamp the safe load or a reference number for the chain load on the ring or hook. Stamp marks should not be placed on chain links as they may form points of weakness in the surface of the links when they are in cold worked condition, which may start a crack. Some chain users weld to the ring or connecting link of the chain a flat link on which the safe load or number may be marked. This flat link does not form a part of the chain to which the load is applied. A greater load can be lifted safely with a given size of chain or sling when the chain or all of the legs of the sling are in a vertical position. Safe working loads for iron sling chains are given in Table 5.

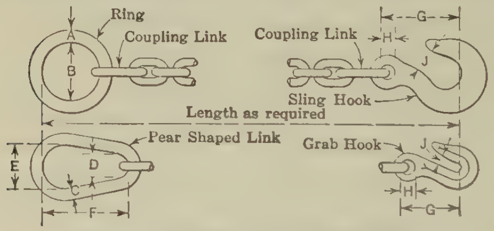

Fig. 7. Dimensions of Single Sling Chains

**IRON SPECIFICATIONS.**—**Grade A Iron Chain** shall be made from all-puddled iron, free from any admixture of iron or steel scrap. The original muck bars shall be twice

piled and rerolled. All bars shall be the full length of the pile. The physical properties of the iron shall be such, when made into chain, as to conform to the breaking loads and elongation called for by specifications A56–30 for iron crane chain. (See p. 6–31.)

**Grade B Iron Chain** shall be rolled from a box pile, top, bottom, and sides of which shall have been rolled from muck bar, and the filler, which consists of muck bar, shall be the full length of the pile. The physical properties shall be as specified for Grade A chain.

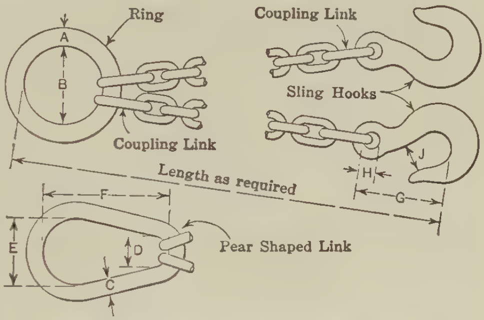

Fig. 8. Dimensions of Double Sling Chains

**LUBRICATION.**—To lessen wear of the chain links when wound on a drum and passed over sheaves, they should be lubricated at frequent and regular intervals with grease or heavy oil mixed with graphite. When lubricating, the chain should be slack and the oil brushed well in between the ends of the links. Grease and oil should not be used in places such as foundries where grit and sand particles are present, resulting in severe abrasive action. Sling chains should not be lubricated, as the lubricant would be transferred to the bodies of men handling the chain, introducing a hazard. The lubricant may also increase the slipping hazard.

**STORAGE.**—When chains are not in use they should be kept in a place suitable for storage. They should not be exposed to corrosive fumes or liquids.

**RINGS, HOOKS, AND END LINKS.**—When hooks, rings, or special end links are used with chain in sustaining loads, care should be taken to select the attachments of the type, grade, and size suitable for service with the size of chain used. Specifications for sling hooks, grab hooks, end rings, and pear-shaped end links given in Tables 6 and 7 are approved by the Chain Institute. It is recommended that they be followed. Forged steel hooks always are preferable, and especially for lifting heavy loads. Cast steel hooks frequently contain such defects as blow holes which cannot be detected by inspection. Hooks of very large capacity frequently are made of laminated steel plate.

**METHOD OF EXAMINATION.**—It is important that all hoisting chains be examined at frequent and regular intervals. The examination should include inspection of the links for stretch, wear, gouge marks, open welds, and especially a careful inspection of the surface to ascertain the need of annealing or normalizing, as indicated by the peened, hammered, or polished surface of the links. The examination should be made by a person conversant with the defects and flaws liable to be found, and who has the knowledge and authority to decide when the chain should be removed from service for repair, annealing, normalizing, or replacement.

**BENT HOOKS.**—Hooks which have become bent, due to overloads, should not be straightened and put back into service. When a hook once is bent the stress in the metal so tends to weaken it that its strength afterward is doubtful. Fig. 9 shows a safety hook on which the locking pawl prevents loads from becoming unhooked, and the point of the hook from fouling.

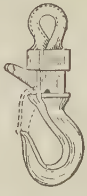

Fig. 9. Safety Hook

**STUD LINK CHAIN.**—Stud link chain, or studded chain, is used only as an anchor chain, and operates over a windlass. It should be made in accordance with the rules of the American Bureau of Shipping.

## 3. WIRE ROPE

The following notes and tables are compiled from data furnished by the American Steel & Wire Co., Cleveland. For further information see catalogs of the American Steel & Wire Co., John A. Roebling's Sons Co., and A. Leschens & Sons Co.

Wire ropes, which have almost entirely superseded chains and manila rope for haulage and hoisting purposes, are made with a varying number of wires to the strand, and a varying number of strands to the rope, according to the service in which they are to be used and the degree of flexibility required. Five grades of rope are usually manufactured, as regards the material used, *viz.*: Iron, cast steel, mild plow steel, plow-steel, and special grades called "Monitor," "Blue center" plow steel, etc. Haulage rope, for mines, docks, etc., usually consists of 6 strands of 7 wires each laid around a hemp core. Hoisting rope, fore levators, mines, coal and ore hoists, conveyors, derricks, steam shovels, dredges, logging, etc., consists of 6 strands of 19 wires each, with a single hemp core. A more flexible rope, for crane service, etc., consists of 6 strands of 37 wires each wound around a single hemp core.

In general, the flexibility of the rope is increased by increasing the number of wires in the strands. The most flexible standard rope made consists of 6 61-wire strands and one hemp core. Other varieties comprise flattened strand ropes for haulage, hoisting, and transmission, non-spinning rope for the suspension of loads at the end of a single line, steel clad rope for severe conditions of service, guy and rigging ropes, and hawsers for towing or mooring.

**BREAKING STRENGTH OF WIRE ROPE.**—The various manufacturers have adopted standard figures for the strength of all sizes and qualities of wire rope. Formerly it was the custom to test the individual wires and to consider their combined strength as the strength of the rope as a whole. These strengths were greater than the actual strength obtained by breaking the finished rope. The figures given in the tables herewith represent actual breaks of the various ropes, and range from 95 to 80% or less of the combined strength of the single wires, depending on the construction.

**LAY OF WIRE ROPE.**—Regular lay of wire rope comprises wires in the strands laid to the left, the strands being laid to the right, known as right-lay rope; or wires laid to the right, and strands laid to the left, known as left-lay rope. Standard rope is made regular lay, right lay. In Lang lay rope the wires in the strands and the strands themselves are laid in the rope in the same direction, either right or left.

Lang lay rope is somewhat more flexible than ordinary rope, and as tne wires are laid more axially in the rope, longer surfaces are exposed to wear, and the endurance thereby is increased. Lang lay rope is used only to a limited extent in the U. S., largely where the ropes drag or are subjected to much friction. As Lang lay rope untwists more readily than regular lay, care must be exercised in its use. It is not as good an all-around rope as regular lay.

**SHEAVES AND DRUMS.**—Drums and sheaves of the largest practicable diameter are recommended in all wire rope installations. See Table 8. If possible, drums should be lagged, and where feasible, a grooved drum on hoists is more desirable than a flat drum. The grooves should give ample clearance between successive windings; thus a drum for $^3/_4$-in. rope should have the grooves at least $^7/_8$-in. apart on centers. The grooves should be made smooth in order not to cut the rope, and they should be of slightly larger radius than the rope in order to avoid wedging or pinching it. See Table 9. Overwinding, that is, the winding of the rope in more than one layer, is to be avoided, if possible, by making the drum large enough to take all the rope in a single layer. Overwinding will rapidly

**Table 8.—Diameter of Sheaves and Drums for Wire Rope**

Diam. of Sheave = (Diam. of Rope × $C$)

| Type of Rope | Values of $C$ | |
|---|---|---|
| | Average Recommended | Minimum |
| 6 × 7 | 72 | 42 |
| 18 × 7 non-spinning | 51 | 34 |
| 6 × 19 | 45 | 30 |
| 6 × 21 | 45 | 30 |
| 6 × 25 | 45 | 30 |
| 6 × 37 | 27 | 18 |
| 8 × 19 | 31 | 21 |

| 7/16 | 1/32 | 1/16 | 7/8 | 1/32 | 1/16 | 1 1/2 | 1/32 | 1/8 | 2 1/8 | 3/64 | 1/8 |
| 1/2 | 1/32 | 1/16 | 1 | 1/32 | 1/16 | 1 5/8 | 1/32 | 1/8 | 2 1/4 | 3/64 | 1/8 |

destroy the rope, and the extra cost of the larger drum will be more than compensated by the greater life of the rope. The best possible alignment of sheaves and drums should be made to avoid undue wear on the sides of the sheaves and the rope. In general, the lead sheaves over which the rope runs from the drum should be aligned with the center of the drum, or if the drum is not entirely filled, with the center of the portion on which the rope is wound. The distance between the drum and lead sheave should be such as to cause an angle not exceeding 1° 30′ between the line from the center of the sheave to the center of the drum, and the line from the center of the sheave to the outer side of the drum. When the sheaves become worn, they should be replaced or the grooves turned before they are used with a new wire rope, otherwise the rope will not work properly. When changing an old rope for a new one, the sheaves should be examined, and if scored or cut from the old rope, they should be turned, relined or renewed, so that the new rope will not receive undue wear. For many purposes, particularly mine service, the grooves can advantageously be lined with well-seasoned, hardwood blocks set on end, which can be renewed when worn. Large sheaves, running at high velocity, should be lined with leather set on end, or with india-rubber. This is the practice for power transmission between distant points, where the rope frequently runs at a velocity of 4000 feet per minute.

**REVERSE BENDING.**—Reverse bending, that is, bending the wire rope first in one direction over sheaves and then in the opposite direction, is to be avoided wherever possible. This practice will wear out a rope more quickly than any other known method. A little care in design usually will eliminate all situations which call for reverse bending, and it is even desirable to change existing constructions if necessary to remove this condition. The expense of rope renewals will more than equal the cost of change, as a rule.

**HANDLING WIRE ROPE.**—Wire rope must not be coiled or uncoiled like hemp rope. When received in a coil it should be rolled on the ground like a hoop and straightened out before being put on the sheaves. If on a reel, it should be mounted on a spindle or a flat turntable and properly unwound. Kinking or untwisting must be avoided.

**PROTECTION AND LUBRICATION OF WIRE ROPE.**—Wire rope should be protected by a suitable lubricant, both externally and internally, to prevent rust and keep it pliable. The lubricant should be suited to the conditions under which the rope is used. It should not contain acids or other corrosive agents, and should readily penetrate the strands. It should be self spreading, adhesive, and water repelling. The higher the speed of the rope, the lower should be the viscosity of the lubricant. For stationary ropes for low speed work, as on shovels, cranes, or derricks, a heavy petroleum oil or grease, viscosity approximately 1000 sec. at 210° F., applied hot, is advised. For heavy haulage, as slope and logging ropes, a lubricant of viscosity of 500 to 800 sec. at 210° F. should be used. For high speed hoisting, as in mine hoists, a lubricant of viscosity of 400 to 500 sec. at 100° F. is recommended, with automatic lubrication. In all cases, the viscosity should be such that the lubricant will cover the rope, penetrate thoroughly, withstand pressure, but yet not so thin as to run off the rope. Crude oils should not be used. New lubricants only should be applied. Lubricants should be applied hot, as the penetration thereby is increased, and when cooled the lubricant exists as a plastic filler to lubricate the wires and to exclude moisture. The lubricant is best applied by passing the rope through a bath of heated oil. Placing a drum of heated oil over the rope and allowing the oil to flow on the rope is wasteful of oil. When hand lubrication is necessary a piece of sheepskin with the wool coat on the inside is recommended as a wiper, the wool being saturated with oil, and held around the rope as it passes through the wiper. While in storage, wire rope should be kept dry and protected from the weather, acid, and acid fumes. When a used rope is stored, it should be thoroughly cleaned before oiling and then treated as a new rope. For special cases, the manufacturers of wire rope should be consulted as to the type and method of lubrication.

**EXPOSURE TO HEAT.**—Where wire rope is exposed to intense heat, as in foundry or steel mill service, a soft iron often is substituted for the hemp core. Asbestos also sometimes is used, but it is not recommended.

## Varieties and Uses of Wire Rope

**GALVANIZED WIRE ROPE** is used for "standing" service, where no bending is required, as guys, ship's rigging, towing and mooring lines, etc. It is not adapted to hoisting service, as the galvanized coating is abraded and worn away by the sheaves, thus promoting corrosion. The more commonly used types of galvanized wire rope are described below.

**Galvanized Standing and Guy Ropes** are made both of iron and cast steel wire. The iron rope comprises 6 strands, 7 wires to the strand, with a hemp core. The cast steel rope comprises 6 strands with either 7 or 19 wires to the strand and a hemp core. Both types also are made with a wire strand center, which increases the breaking strength about 7.5%. These ropes also are known as yacht rigging rope. See Table 10.

**Galvanized Steel Strand** is made with 7 or 19 steel wires twisted into a single strand. The standard grade is used for guys for smokestacks and poles and for supporting trolley wires and operating railroad signals. The Siemens-Martin high strength, and extra high strength grades combine high strength with toughness and light weight. They are used to guy electric railway, telegraph and telephone poles, to support trolley and messenger wires, and for purposes where high strength is required. See Table 13.

* 7 wire. † 19 wire.

**TRANSMISSION OR HAULAGE ROPE.**—Usually made of 6 7-wire strands and one hemp core, in all five grades. It is made of large wires and is the least flexible of any standard rope. Cast steel rope is particularly adapted to mine haulage work, including tail rope and endless haulage systems, gravity hoists, and coal and ore dock haulage, roads, operating small grip cars, etc. The sizes 3/8 to 5/8 in. inclusive, are used for sand lines in oil wells, and from 5/8 to 1 in. for oil-well drilling. In general, it can be used for severe service, and where the flexibility required is a minimum. The plow-steel rope is advised for situations similar to those for which the cast steel ropes are used, but where it is necessary to secure increased strength, without altering the working conditions. The wires are harder and capable of standing greater wear than any of the foregoing ropes. Monitor plow-steel rope is the strongest and stiffest of all and is used for work demanding the greatest strength and lightest rope possible. Sheaves for this rope should, if possible, be somewhat larger than for other grades. For working loads, strength, etc., of these ropes, see Tables 15 and 16.

**Standard Hoisting Rope.**—Composed of 6 19-wire strands and a hemp core; made in the following grades: Iron, cast steel, mild plow steel, plow steel and Monitor plow steel. The wires are smaller than those in transmission ropes of the same size, and the rope is more flexible. It will not stand as much abrasion as transmission rope. The hemp-center rope is very pliable and will wind on moderate size drums and sheaves without injury. If possible, drums and sheaves should be larger than shown in Table 8. The cast steel, mild plow steel, plow steel and Monitor plow steel ropes are adapted to mine hoisting, logging, quarrying, elevators, derricks, hay presses, dredges, cableways, inclined planes, coal hoists, conveyors, ballast unloaders, skip hoists, and similar applications. See Table 16.

**Extra Flexible Hoisting Rope.**—Consists of 8 19-wire strands and one hemp core. The greater flexibility permits its use on smaller sheaves and drums, such as usually are found on derricks. It is not advisable to use it where there is much overwinding, as it will flatten much more quickly than the 6 × 19 standard rope. It is made in the five grades of iron, cast steel, mild plow steel, plow steel, and Monitor plow steel. Its uses are the same as those of standard hoisting rope. See Table 17.

**Special Flexible Hoisting Rope.**—Consists of 6 37-wire strands and one hemp core. It is extremely flexible, and is especially adapted to high-speed service on cranes, or where sheaves are small. It is made in the grades cast steel, mild plow steel, plow steel, and Monitor plow steel. It will not stand as much abrasion as the 6 × 19 rope, but it is particularly efficient, as over 50% of the wires are in the inner layers and are protected from abrasion. The cast steel ropes are used for general hoisting work where the sheaves are small, while the plow steel varieties are recommended for crane service. The Monitor plow steel rope is largely used on dredges for both main and spud ropes. See Table 18.

| 1/2 | .39 | 6.5 | 7.1 | 8.8 | .45 | 8.1 | 8.8 | 11.0 | .39 | 6.5 |
| 3/8 | .22 | 3.7 | 4.0 | 5.1 | .25 | 4.6 | 5.0 | 6.35 | .22 | 3.7 |

**FLATTENED STRAND ROPE.**—Flattened strand ropes are used where an increased wearing surface is desired above that obtained with a round strand rope. The wearing surface in contact with sheave or drum is from 100 to 150% greater than in round-strand ropes.

**Flattened-strand Haulage or Transmission Rope** is made in three types, each with a hemp core. Type C has 5 9-wire strands, the center wire being of elliptical cross-section; type D has 6 8-wire strands, the center wire being of triangular cross-section; type E has 5 11-wire strands, the three center wires being of smaller diameter than the others and laid alongside of each other in the same plane. These ropes also are made with a wire strand or wire rope center, which increases the breaking strength about 7.5%. See Table 19.

**Flattened-strand Hoisting Rope** is made in two types each with a hemp core. Type A consists of 5 strands, 28 wires per strand, the center wire being of elliptical cross-section, and the inner layer of surrounding wires being of smaller diameter than the outer. Type B consists of 6 strands, 25 wires per strand, the center wire being of triangular cross-section, and the inner layer of surrounding wires being of smaller diameter than the outer layer. Type A sometimes is used on elevators and on some types of coal handling equipment. It is not adapted to general hoisting, especially when used for heavy service over flat sheaves or drums, or where overwinding occurs. Type B is a very rigid rope that holds its shape well under stress. It easily can be passed over sheaves of moderate size. Both types are made in the iron, cast steel, mild plow steel, plow steel and Monitor plow steel grades. When made with a steel rope or steel strand center, the breaking strength is increased about 7.5%. See Table 20.

**Non-spinning Hoisting Rope.**—Comprises 18 7-wire strands and one hemp core, 6 strands, Lang lay, being laid around the core to the left, and 12 strands, regular lay being laid to the right around them. A free object suspended from the end of a rope of this character will not rotate and endanger the lives of persons below it. Furthermore, the attention required to handle and guide the load is decreased. This rope is recommended for back haul or single-line derricks, and for shaft sinking and mine hoisting, where the bucket swings without guides. This rope works best where it does not overwind on the

drum. The best fastening is an open or closed socket, but the wire rope makers recommend that fastenings be attached at the factory. This rope should not be as heavily loaded as ordinary hoisting rope. It is made in the grades of cast steel, mild plow steel, plow-steel, and Monitor plow-steel. See Table 21.

**ELEVATOR ROPE.**—Table 22 gives the characteristics of elevator hoisting rope, both standard and Seale construction. Seale construction consists of a single center wire, surrounded by a circle of wires of the same diameter, with a circle of smaller filler wires interposed between the center and outer wires.

**MARLIN-CLAD ROPE.**—This is a round strand rope, each strand being given an external serving of tarred marlin. (See Table 23). It is particularly adapted for ship rigging, cargo hoists, power transmission (see page 24–53), grain shovels, etc. It is considerably stronger than manila rope of equal diameter, a 1-in. plow-steel marlin-clad rope having a strength of 26,400 lb., while that of a 1-in. manila rope is 7500 lb. Marlin-clad rope weighs approximately 30% less than manila rope of the same strength.

**Marlin-clad Hawser Rope** consists of 5 separate ropes around a hemp core. Each rope comprises 5 strands, 7 wires per strand and one hemp core, covered with an external serving of tarred marlin. It is made in plow steel, mild plow steel and cast steel grades. See Table 24.

**STEEL-CLAD HOISTING ROPE.**— The regular grades of hoisting ropes, as well as the special flexible, are made, if desired, with a flat strip of steel wound spirally around each strand. These strips give additional wearing surface without sacrificing the flex-

ibility. When the flat winding is worn through, a complete rope remains with unimpaired strength. These ropes are designed for severe conditions of service, and an additional service of 50 to 100% over that of the unprotected rope frequently is obtained. Tables 15 to 18 may be used for the strength of steel-clad rope, by referring to the diameter of the rope, as it would be were no wrapping applied. The standard steel-clad hoisting rope is made in sizes (diam. of bare rope) of 1/2 to 2 in. See Table 16. The special flexible steel-clad rope is made in sizes (diam. of bare rope) of 7/8 to 2 1/4 in. See Table 18. The steel wrapping is not considered as adding any strength to the rope but merely serving to increase its life. This rope is made in two grades of plow steel and Monitor plow steel.

**FLAT ROPE.**—Flat rope consists of a number of "flat-rope" strands, twisted alternately right and left, placed side by side and sewed with soft Swedish iron or steel wire, to form a flat rope of the desired width and thickness. The soft sewing wires wear much quicker than the rope wire, and have to be replaced from time to time, at which time worn strands can also be renewed. Flat rope is used principally for hoisting heavy loads out of deep shafts, it requiring a reel but little larger than the width of the rope, whereas round rope necessitates the use of a large drum. Its use is recommended where saving of machinery space is an object. It does not twist or spin in the shaft. It is also used for operating spouts on coal and ore docks, and for raising and lowering emergency gates on canals and similar machinery. For details of methods of fastening it to drums, the manufacturers should be consulted. Drums and sheaves should be as large as possible. A rule for the diameter of the drum is $D = ct$, where $D$ is diameter of drum at bottom, in., $t$ = thickness of rope, in., and $c$ = 100 for drums and 160 for sheaves. Sheaves should be crowned at the center and have deep flanges to guide the rope. See Table 25.

**TOWING AND RUNNING ROPES** are made of 6 12-, 24-, or 37-wire strands with a hemp core in each strand. See Table 26. They are lighter than hemp hawsers of equal strength and are flexible enough to work around the same bitts as hemp rope of equivalent strength. The following is a comparison of hawsers of equal strength:

| | Tarred Russian Hemp | White Manila Hawser | 4-in. Galv. Steel Hawser | Studded Link Chain |
|---|---|---|---|---|
| Weight per fathom, lb. | 39 | 18 | 13 | 68 |
| Circumference, in. | 13 | 10 | 4 | 1 1/8 diam. |

**TRACK STRAND FOR AERIAL TRAMWAYS.**—Composed of several successive layers of wires wrapped around a single wire core, the number of wires varying with the diameter of the cable. The cable is made in plow steel and cast steel grades. See Table 27.

**LOCKED WIRE CABLE.**—Locked wire cable and locked coil track cable, of the general form shown in Fig. 10, are used as track cables for aerial tramways. They differ only in the number and size of wires used, and both are made of cast steel. The locked wire cable is the more flexible of the two. These cables are smoother than the track cable described above. See Table 28.

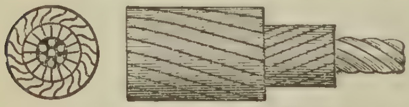

Fig. 10. Locked Wire Cable

## Wire Rope Fittings

**Wire Rope Splices and Fittings.** (See also page 23–10.)—Three types of splices are used with wire rope—the end-to-end, the endless, and the thimble splice. The first two may be either long or short splices. The end-to-end splice is used to attach one rope to another by interlocking the strands, as shown on page 6–46. Ropes of similar construction can be so spliced, but a right lay rope cannot be spliced into a left lay rope. In making a splice a certain amount of rope is used up. The additional length to be allowed for a splice is shown in Table 29.

The endless splice is made in the same manner as the end-to-end splice.

The thimble splice is the forming of a loop in the end of a rope and then interlocking the strands, the loop usually containing a thimble or other fitting. Dimensions of thimbles are given in Table 30.

**Shackles** are used to connect ropes whose ends are equipped with thimble sockets, turnbuckles, etc. See Table 31. Select the size of shackle whose strength is equal to that of the rope to be used with it.

### Table 29.—Length of Wire Rope to be Allowed for Splices

Shackle Thimble Open Socket Closed Socket

FIG. 11. Wire Rope Fastenings

**Clips** are fastenings usually used to form a thimble loop where the use of the rope is temporary. The U-bolt of the clip should rest on the short end of the rope so that the flat bears on the tension side of the loop. Otherwise the rope will be injured by the clip putting a crimp in the tension side. Not less than 2, and preferably 4 or 6 clips should be used, especially on the larger diameters of rope.

**Clamps** are temporary fastenings, usually used to form loops without thimbles. From 2 to 6 clamps should be used for each end fastening, and alternate clips and clamps are preferable.

**Turnbuckles** are necessary where slack in rope is to be taken up or a uniform tension maintained. The turnbuckles should always be equal in strength to that of the rope used with them. See Table 32 for dimensions and strength. Where a greater take-up is required than that given in the table, two or more turnbuckles should be used. Turnbuckles are usually made with the styles of ends shown in Fig. 12.

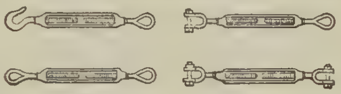

FIG. 12.. Turnbuckles

**Sockets** are the strongest type of rope fastening. Dimensions of closed and open sockets are shown in Table 33. Bridge sockets of both open and closed type are also

made for bridge cables and locked tramway and cableway strand. For dimensions, see catalog of American Steel & Wire Co. Sockets develop the full strength of the rope, and are stronger than any rope that may be inserted in them. See below for directions for attaching sockets.

**ATTACHING SOCKETS TO WIRE ROPE.**—The rope should be seized at the end before cutting off and also at a distance equal to the length of the socket basket from the end, the first seizing being removed after the rope is cut off. The seizing in large ropes should be several inches long and securely wrapped with a special seizing iron to prevent untwisting of the lay of the rope, with consequent unequal tension on the strands after the socket is applied. The hemp center is cut out, back to the seizing and the wires broomed out straight, *i.e.*, untwisted, not necessarily straightened. The wires should be cleaned with benzine, naphtha or gasoline, and then dipped for 30 seconds in a bath of commercial muriatic acid. They should next be dipped in boiling water containing a small amount of soda to neutralize the acid, and then inserted in the basket of the socket. The socket should line up with the axis of the rope. After sealing its base with clay, putty or similar substance, the socket is filled with molten zinc, at a temperature not exceeding 875° F. If socketing is properly done, one or more strands of the rope will break before the socket fails. See also Bureau of Mines Bulletin No. 75, page 124.

FIG. 13

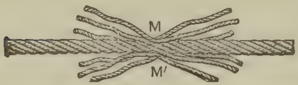

FIG. 14

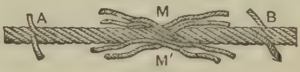

FIG. 15

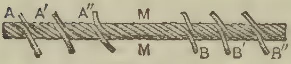

FIG. 16

FIG. 17

Splicing Wire Rope.

**TO SPLICE A WIRE ROPE.**—The tools required will be a small marline spike, cutting nippers, and either clamps or a small hemp-rope sling with which to wrap around and untwist the rope. If a bench-vise is accessible it will be found convenient. In splicing a rope, a certain length is used up in making the splice. See Table 29.

Having measured, carefully, the length the rope should be after splicing, and marked the points *M* and *M′*, Fig. 13, unlay the strands from each end *E* and *E′* to *M* and *M′* and cut off the center at *M* and *M′*, and then:

(1) Interlock the six unlaid strands of each end alternately and draw them together so that the points *M* and *M′* meet, as in Fig. 14.

(2) Unlay a strand from one end, and following the unlay closely, lay into the seam or groove it opens the strand opposite it belonging to the other end of the rope, until within a length equal to three or four times the length of one lay of the rope, and cut the other strand to about the same length from the point of meeting as at *A*, Fig. 15.

(3) Unlay the adjacent strand in the opposite direction, and following the unlay closely, lay in its place the corresponding opposite strand, cutting the ends as described before at *B*, Fig. 15.

There are now four strands laid in place terminating at *A* and *B*, with the eight remaining at *MM′*, as in Fig. 15. It will be well after laying each pair of strands to tie them temporarily at the points *A* and *B*.

Pursue the same course with the remaining four pairs of opposite strands, stopping each pair about eight or ten turns of the rope short of the preceding pair, and cutting the ends as before.

We now have all the strands laid in their proper places with their respective ends passing each other, as in Fig. 16. All methods of rope-splicing are identical to this point: Their variety consists in the method of tucking the ends. The one given below is the one most generally practiced.

Clamp the rope firmly in a vise at a point to the left of *A*, Fig. 16, and by a hand-clamp applied near *A*, open up the rope by untwisting sufficiently to cut the core at *A*. The core is seized with the nippers, and drawn out slowly. The core is followed closely by the strand, which is crowded in the place of the core, until it is all laid in. Cut the core where the strand ends, and push the end back into its place. Remove the clamps and let the rope close together around it. Draw out the core in the opposite direction and lay the other strand in the center of the rope, in the same manner. Repeat the operation at the five remaining points and hammer the rope lightly at the points where the ends pass each other at *A*, *A′*, *B*, *B′*, etc., with small wooden mallets, and the splice is complete, as shown in Fig. 17. If a clamp and vise are not obtainable, two rope slings and short wooden levers may be used to untwist and open up the rope.

A rope spliced as above will be nearly as strong as the original rope and smooth everywhere. After running a few days, the splice, if well made, cannot be found except by close examination. The above instructions have been adopted by the leading rope manufacturers of the U. S.

Notes:—Length of all types of rivets made as ordered. Radius of head of button head rivets $r = 0.885\,D$. Radii of head of pan head rivets, $r_1 = 0.314\,D$; $r_2 = 0.85\,D$; $r_3 = 3.43\,D$. Radius of head of truss rivets, $r = 2.512\,D$. Rivets are to be made of open-hearth steel of 45,000 to 55,000 lb. per sq. in. tensile strength; yield point of 0.5 × tensile strength; minimum elongation in 8 in., 1,500,000 ÷ tensile strength; manganese 0.30 to 0.50%; phosphorus $< 0.04\%$; sulphur $< 0.05\%$; rivets to test between Nos. 20 and 26 scleroscope (Shore).

## SIMPLE STRESSES

### 1. DEFINITIONS

**STRESS OR TOTAL STRESS** is the resultant internal force that resists change in the size or shape of a body acted on by external forces. If the external forces acting on the body increase to the extent that the maximum stress that can be developed is unable to balance the external forces, the body will break or rupture. Stresses are measured in the same units as the forces which produce them, *i.e.*, pounds, tons, etc.

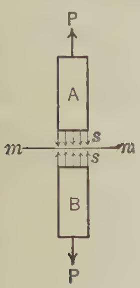

Fig. 1

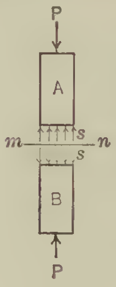

Fig. 2

**UNIT STRESS** is the stress per unit of area. Its value at any point of a section is the stress on an elementary part of the area, including the point, divided by the elementary area, and generally varies from point to point of the section. When the stress $P$ is uniformly distributed over an area $A$, the unit stress $S$ at any point of the area is $P/A$. Unit stresses are expressed in pounds per square inch, tons per square foot, kilograms per square centimeter, etc.

**TENSILE STRESS OR TENSION** is the internal force that resists the action of external forces tending to increase the length of a body. Tension is developed in a bar when the external forces $P$ act on it in the directions away from its ends. See Fig. 1. The tendency is to separate the bar into two parts $A$ and $B$. To maintain equilibrium each part is acted on at section *mn* by tensile stresses, $s$. The resultant of $s$ is equal and opposite in direction to the resultant of the forces, $P$. If the forces acting on one end of the bar total 1000 lb. then the stress on the section *mn* equals 1000 lb.

**COMPRESSIVE STRESS OR COMPRESSION** is the internal force that resists the action of external forces tending to decrease the length of a body. Compression is developed in a bar when external forces $P$ act on it in the directions toward its ends. In Fig. 2, the tendency of the external forces $P$ is to shorten the bar by pushing any two parts, as $A$ and $B$, closer together. As long as equilibrium is maintained, the resultant of the compressive stresses acting on either part at section *mn* is equal and opposite in direction to the resultant of the external forces acting at the end of the part considered.

**SHEARING STRESS OR SHEAR** is the internal force acting along a plane between adjacent parts of a body, when two equal forces, parallel to the plane considered, act on each part in opposite directions. The shear resists the tendency of one part to slide over the other part. In Fig. 3, the projecting part of the cantilever beam $A$ is acted on by external vertical forces due to the weight of $A$ and any loads that it carries. The resultant $P$ of these forces is equal, parallel to, and opposite in general direction to the upward pressure or reaction $R$ which acts on the part of the beam embedded in the wall. There exists, therefore, a tendency of the parts to assume the relative positions shown in Fig. 3. An internal force, or shear, acting along the cross-section *mn* resists the tendency of $A$ to slide vertically downward. As long as equilibrium is maintained, if $P$ equals 1000 lb., $R$ also equals 1000 lb., and the shear acting on the section will be equal to 1000 lb.

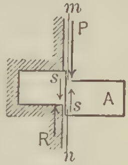

Fig. 3

**SIMPLE STRESS.**—Tension, compression, and shear are considered singly and in combination in engineering practice. When one of these is considered singly, the case is one of simple stress.

**NORMAL STRESS** is a stress that acts in a direction perpendicular to the section considered.

**AXIAL STRESS** is the stress existing in a straight homogeneous bar when the resultant of the applied loads coincides with the axis of the bar. The stress is distributed uniformly over any section normal to the axis of the bar.

**AXIAL TENSION** exists in a vertical bar supported only at its upper end. If the resultant of the applied load does not coincide with the axis of the bar, the stress is not uniform over the cross-section of the bar. A bar held in an inclined position, even though subjected to axial force applied at its ends, is not in simple axial tension, since the weight of the bar itself is an external force acting on it at an angle to its axis, and the stress is not uniform over a cross-section of the bar.

**AXIAL COMPRESSION** exists in a pier or prism of length not over 6 to 8 times the least side or diameter, when the resultant of the load supported acts through the centers of gravity of the end sections. When the length is greater than 6 or 8 times the least side or diameter, the pier is regarded as a column in which some bending has taken place. The stresses then are not uniformly distributed over a cross-section and the case is not one of simple axial compression.

**DEFORMATION** is the amount of the change in the shape of a body caused by the application of external forces. When the external forces cause tension, the deformation is the amount that the body is increased in length (elongation); when they cause compression, it is the amount that the body is decreased in length (shortening); when they cause shear, it is the amount that one part of the body slips over the adjacent part (detrusion). Deformations are measured by the same units of length used in measuring the linear dimensions of the body.

**Unit Deformation,** or deformation per unit of length, is the total amount of deformation divided by the original length of the body before the load causing the deformation was applied. Unit deformation is designated by $\epsilon$.

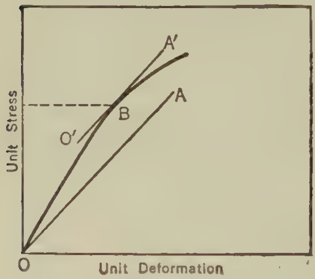

Fig. 4

Ultimate unit deformation is the unit deformation measured after the body has ruptured, expressed as a percentage of original length.

**HOOKE'S LAW** states that a body acted on by external forces will deform in proportion to the stress developed, so long as the unit stress does not exceed a certain value, which varies for the different materials. This value is the *proportional limit.*

**PROPORTIONAL LIMIT** is that unit stress at which unit deformation begins to increase at a faster rate than does unit stress; or it is the highest unit stress at which stress is proportional to deformation. It is determined by noting, on a stress-deformation diagram, the unit stress at which the curve departs from a straight line.

**ELASTIC LIMIT** is the maximum unit stress to which a material may be subjected and still be able to return to its original form upon the removal of the stress. When stressed beyond the elastic limit, a body will return to its original form only partially and thereby acquires a permanent deformation or "set."

The determination of the elastic limit logically involves the application and release of a series of increasing loads until a set is observed after the release of a load. This procedure is very slow; and, since for many metals, there seems to be no significant difference between the elastic limit so determined and the proportional limit, the latter often is accepted as equivalent to the elastic limit, and frequently is called the *proportional-elastic limit.* There is, however, no fundamental relation between the elastic limit and the proportional limit. In many of the older tests, particularly with timber, the proportional limit was incorrectly reported as the elastic limit.

**Johnson's Apparent Elastic Limit.**—In view of the difficulty of determining precisely for some materials the proportional limit, J. B. Johnson proposed as the "apparent elastic limit," the point on the stress-deformation diagram at which the rate of deformation is 50% greater than at the original. It is determined by drawing $OA$, Fig. 4, with a slope with respect to the vertical axis 50% greater than the straight-line part of the curve; the unit stress at which a parallel $O'A'$ to this line is tangent to the curve (point $B$, Fig. 4) is the apparent elastic limit.

**YIELD POINT** is the unit stress at which deformation first increases markedly without any increase in the applied load. The yield point is always above the proportional limit and true elastic limit.

Ductile metals have a well-defined yield point which is practically the same value as the proportional limit. For this reason, and because of the method of commercial testing, the yield point of ductile metals sometimes is reported as the elastic limit, or as the *commercial elastic limit.*

A.S.T.M. Standards, 1933, E8–33, specify that the term *yield point*, shall not be used in connection with material whose stress-deformation curve in the region of yield is smooth and of gradual curvature.

**YIELD STRENGTH** is the unit stress at which a material exhibits a specified limiting permanent set. It is a measure of the useful limit of materials, particularly of those whose stress-deformation curve in the region of yield is smooth and of gradual curvature.

**ULTIMATE STRENGTH,** (tensile or compressive strength), is the highest unit stress a material can sustain before rupturing.

**THE POINT OF RUPTURE,** or breaking strength, is the unit stress at which a material breaks or ruptures. It is observed in tests on steel to be slightly less than the ultimate strength, because of the large reduction in area before rupture.

**STRESS-DEFORMATION DIAGRAM.**—The relation between unit stress and unit deformation is shown by a stress-deformation diagram, in which ordinates to a curve represent unit stresses, and abscissas represent the resulting unit deformations for all values of unit stress to the point of rupture.

Fig. 5 shows a typical tension stress-deformation curve for medium steel. The proportional limit is at $a$, the yield point is at $b$, the point of ultimate stress is at $c$, and the point of rupture is at the end of the curve. The form of the curve obtained from a test will vary according to the material tested, and will be different for compression than for tension. For some materials, like cast iron, concrete, and frequently, timber, no part of the curve is a straight line.

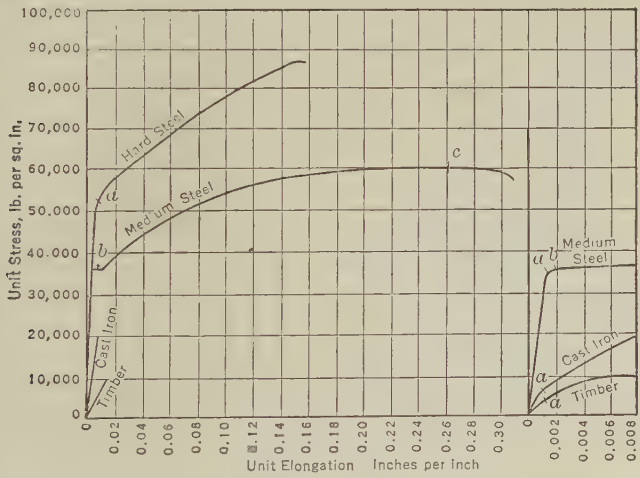

FIG. 5. Stress-Deformation Diagram.

**MODULUS OF ELASTICITY** in tension or compression is the constant which expresses the ratio of unit stress to unit deformation for all values of unit stress not exceeding the proportional limit of a material. The terms *coefficient of elasticity* and *Young's modulus* sometimes are used to express this ratio.

The deformation caused by any unit stress not exceeding the proportional limit may be computed if the modulus of elasticity is known. If a bar of length $l$ and cross-sectional area $A$ be acted on by an axial load $P$ to produce a total deformation $e$, the unit stress is $P/A$, and the unit deformation is $e/l$. Let $E$ = modulus of elasticity, $s$ = unit stress, and $\epsilon$ = unit deformation; then

$$E = \frac{\text{Unit stress}}{\text{Unit deformation}} = \frac{s}{\epsilon} = \frac{P/A}{e/l} = \frac{Pl}{Ae} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [1]$$

or

$$e = \frac{Pl}{AE} = s\frac{l}{E} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [2]$$

This formula can be used only for unit stresses not greater than the proportional limit, because for higher unit stresses the ratio $s/\epsilon$ is not constant. The modulus of elasticity $E$ is a measure of the stiffness of a body, or of its ability to resist deformation within the proportional limit of the material. The greater the modulus of elasticity the less will be the deformation for any unit stress not exceeding the proportional limit.

For any given material, the modulus of elasticity often is the same in tension or compression.

Average values for steel and wrought iron are respectively 30,000,000 lb. per sq. in. and 25,000,000 lb. per sq. in. See p. 1–05 and Sections 4 and 5 for values for other materials. Axial stresses always are implied when the unqualified term "modulus of elasticity" is used.

**Modulus of Elasticity in Shear.**—The expression for the modulus of elasticity in shear is similar to that for tension or compression; the deformation, however, is in a direction lying in the plane of shear of the body. The modulus of elasticity in shear also is called the *modulus of rigidity.*

Let $E_s$ = shearing modulus of elasticity, $s_s$ = unit shearing stress, $e_s$ = total lateral deformation or detrusion due to the shear, and $\epsilon_s$ = unit detrusion. Then

$$E_s = \frac{\text{Unit shearing stress}}{\text{Unit detrusion}} = \frac{s_s}{\epsilon_s} = \frac{P/A}{e_s/l} = \frac{Pl}{e_s A} \quad \text{[3]}$$

or

$$e_s = \frac{Pl}{AE_s} = \frac{s_s l}{E_s} \quad \text{[4]}$$

For metals, the shearing modulus of elasticity is approximately 0.4 times the tensile modulus of elasticity.

**POISSON'S RATIO** is the ratio of lateral unit deformation to linear unit deformation, within the elastic limit. It also is known as the *factor of lateral contraction.* See Fig. 6.

It has been established by experiment that the lateral unit deformation is proportional to the linear elongation or shortening. Let $\lambda$ = Poisson's ratio; $d$, $d_1$ = respectively, diameter of bar before and after elongation or shortening; $l$, $l_1$ = respectively, length of bar before and after elongation or shortening; $\epsilon$ = longitudinal unit elongation or shortening, as the case may be. Then

For tension.............. $l_1 = (1 + \epsilon)l$; $d_1 = (1 - \lambda\epsilon)d$ . . . . . . . . . [5]

For compression.......... $l_1 = (1 - \epsilon)l$; $d_1 = (1 + \lambda\epsilon)d$ . . . . . . . . . [6]

Average values of Poisson's ratio for the usual materials of construction are:

| Material.......... | Steel | Wrought Iron | Cast Iron | Brass | Concrete |
|---|---|---|---|---|---|
| Poisson's ratio..... | 0.333 | 0.333 | 0.25 | 0.333 | 0.10 |

**ELASTICITY** is the property of a material that enables it to deform and return to its original shape upon the removal of the load.

**DUCTILITY AND MALLEABILITY** often are used synonymously. Specifically, ductility is the ability of a material to sustain large permanent deformations in tension, as drawing into a wire; malleability is the ability to sustain large permanent deformations in compression, as beating or rolling into thin sheets.

**PLASTICITY** is that quality of a material that permits of its being molded.

A material is plastic if the smallest load produces a permanent deformation. A perfectly plastic material is non-elastic, and has no ultimate strength in the ordinary meaning of that term. Lead is a plastic material; a prism tested in compression will deform permanently under a small load, and will continue to deform as the load is increased, until it flattens to a thin sheet. Wrought iron and steel are plastic when stressed beyond the elastic limit in compression. When stressed beyond the elastic limit in tension, they are partly elastic and partly plastic, the degree of plasticity increasing as the ultimate strength is approached.

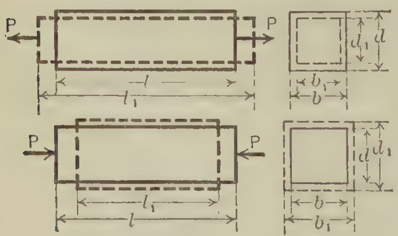

FIG. 6

**BRITTLENESS** is that property of a material that permits it to be only slightly deformed without rupture.

Brittleness is relative, no material being perfectly brittle, that is, capable of no deformation before rupture. Many materials are brittle to a greater or less degree, glass being one of the most brittle of materials. Brittle materials have relatively short stress-deformation curves. Of the common structural materials, cast iron, brick, and stone are brittle in comparison with steel.

**BRITTLENESS AND PLASTICITY** are opposite terms. Materials which have a high degree of plasticity have no brittleness, and they rupture with considerable reduction of area. The reduction of area at rupture may be considered the measure of the plasticity or brittleness of a material, a large reduction of area indicating a high degree of plasticity, and little or no reduction of area indicating a high degree of brittleness.

**TOUGHNESS** is the ability to withstand high unit stress together with great unit deformation, without complete fracture. The area $OAGH$, or $OJK$, under the curve of the stress-deformation diagram, Fig. 7, is a measure of the toughness of the material. The distinction between ductility and toughness is that ductility deals only with the ability to deform, whereas toughness considers both the ability to deform and the stress developed during deformation.

**STIFFNESS** is the ability to resist deformation under stress. The modulus of elasticity is the criterion of the stiffness of a material.

**HARDNESS** is the ability to resist very small indentations, abrasion, and plastic deformation. There is no single measure of hardness, as it is not a single property but is a combination of several properties.

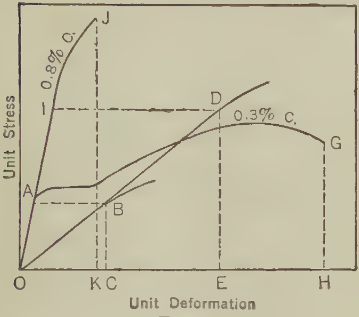

FIG. 7

**CREEP OR FLOW OF METALS** is a phase of plastic or inelastic action. Some solids, as asphalt or paraffin, flow appreciably at room temperatures under extremely small stresses; zinc, lead and tin show signs of creep at room temperature under moderate stresses. At sufficiently high temperatures, practically all metals creep under stresses which vary with temperature, the higher the temperature the lower being the stress at which creep takes place. The deformation due to creep continues to increase indefinitely and becomes of extreme importance in members subjected to high temperatures, as parts in turbines, boilers, superheaters, etc.

**Creep Limit** is the maximum unit stress under which unit distortion will not exceed a specified value during a given period of time at a specified temperature. A value much used in tests, and which has been suggested as a standard for comparing materials, is the maximum unit stress at which creep does not exceed 1% in 100,000 hours.

**TYPES OF FRACTURE.**—A bar of brittle material, as cast iron will rupture in a tension test, in a clean sharp fracture with very little reduction of cross-sectional area and very little elongation. See Fig. 8*a*. In a ductile material, as structural steel, the reduction of area and elongation are greater. See Fig. 8*b*. In compression, a prism of brittle material will break by shearing along oblique planes; the greater the brittleness of the material, the more nearly will these planes parallel the direction of the applied force. Figs. 9*a*, *b*, and *c*, arranged in order of brittleness, illustrate the type of fracture in prisms of brick, concrete, and timber. Fig. 9*d* represents the deformation of a prism of plastic material, as lead, which flattens out under load without failure.

## 2. WORK AND RESILIENCE

**EXTERNAL WORK.**—Let $P$ = axial load, lb., on a bar, producing an internal stress not exceeding the elastic limit; $s$ = unit stress produced by $P$, lb. per sq. in.; $A$ = cross-sectional area, sq. in.; $l$ = length of bar, in.; $e$ = deformation, in.; $E$ = modulus of elasticity; $W$ = external work performed on bar, in.-lb. = $^1/_2\,Pe$. Then

$$W = {}^1/_2\,As\,(sl/E) = {}^1/_2\,(s^2/E)\,Al \qquad . \; . \; . \; . \; . \; . \; . \qquad [7]$$

The factor $({}^1/_2\,s^2/E)$ is the work required per unit volume, the volume being $Al$; it is represented on the stress-deformation diagram by the area $ODE$ or area $OBC$, Fig. 7, in which $DE$ and $BC$ are ordinates representing the unit stresses considered.

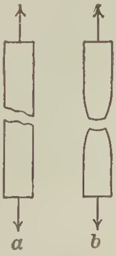

FIG. 8

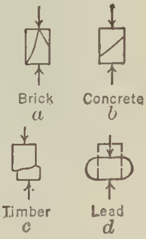

FIG. 9

**RESILIENCE** is the stress energy which may be recovered from a deformed body when the load causing the stress is removed. Within the proportional limit, the resilience is equal to the external work performed in deforming the bar, and may be determined by formula [7]. When $s$ is equal to the proportional limit, the factor $({}^1/_2\,s^2/E)$ is the *modulus of resilience, i.e.*, the measure of capacity of a unit volume of material to store stress energy up to the proportional limit. Average values of the modulus of resilience under tensile stress are given in Table 1.

The total resilience of a bar is the product of its volume and the *modulus of resilience*. The above formulas for work performed on a bar, and its resilience, do not apply if the unit stress is greater than the proportional limit.

**Work Required for Rupture.**—Since beyond the proportional limit the deformations are not proportional to the stresses, $^1/_2\,P$ does not express the mean value of the force

Table 1. Average Values of Tensile Modulus of Resilience and Toughness

| Material | Modulus of resilience, in.-lb. per cu. in. | Relative toughness (area under curve of stress-deformation diagram) |
|---|---|---|
| Gray cast iron | 1.2 | 70 |
| Malleable cast iron | 17.4 | 3,800 |
| Wrought iron | 11.6 | 11,000 |
| Low-carbon steel | 15.0 | 15,700 |
| Medium-carbon steel | 34.0 | 16,300 |
| High-carbon steel | 94.0 | 5,000 |
| Ni–Cr steel, hot-rolled | 94.0 | 44,000 |
| Vanadium steel, 0.98% C, 0.2% V, heat-treated | 260.0 | 22,000 |
| Duralumin, 17 ST | 45.0 | 10,000 |
| Rolled bronze | 57.0 | 15,500 |
| Rolled brass | 40.0 | 10,000 |
| Oak | 2.3* | 13* |

* Bending.

acting. Formula [7], therefore, does not express the work required for deformation after the proportional limit of the material has been passed, and cannot express the work required for rupture. The work per unit volume required to produce deformations beyond the proportional limit or for rupture may, however, be determined from the stress-deformation diagram, as it is measured by the area included between the axis of abscissas, and the stress-deformation curve up to the deformation in question, as *OAGH* or *OJK*, Fig. 7. This area, however, does not represent the resilience, since part of the work done on the bar is present in the form of heat and cannot be recovered.

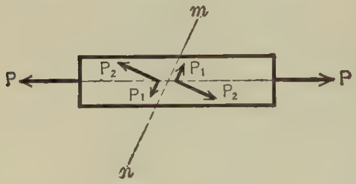

FIG. 10

## 3. COMBINED ELEMENTARY STRESSES

**SHEAR DUE TO AXIAL STRESS.**—An axial load on a bar causes normal stress on the cross-sections, and both normal and shearing stress on inclined sections. In Fig. 10, the component $P_1$ of axial stress $P$, acting parallel to the plane *mn* causes shear on section *mn*. Component $P_2$ acting perpendicular to *mn* causes normal stress on it. Shear will be zero if *mn* is at 0 or 90° to the axis. It will be maximum when *mn* is at 45°, and have the value $s_{s\,\max.} = {}^1/_2\,(P/A)$, $A$ being the area of the bar.

**COMBINED AXIAL STRESSES.**—Assuming tensile stresses to be positive and compression stresses negative, the normal stress on a section due to several applied axial loads is equal to the algebraic sum of the normal stresses caused by each load.

EXAMPLE.—If axial loads $P_1$, $P_2$, $P_3$, and $P_4$ cause unit stress on the cross-section of bar equal to $-20{,}000$, $+12{,}500$, $-6000$, and $+8000$ lb. per sq. in., respectively, the normal axial unit stress is $-5500$ lb. per sq. in. A negative sign indicates that the combined stress is compression.

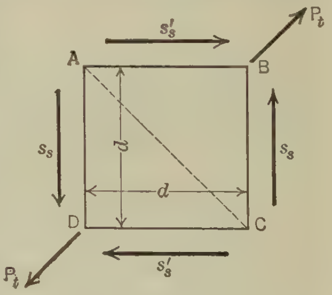

FIG. 11

**SHEAR DUE TO NORMAL STRESSES AT RIGHT ANGLES.**—When two forces act on a body in directions at right angles to each other, causing unit stresses $s_1$ and $s_2$ (tensile stress considered positive and compressive stress negative) on planes normal to the direction of the applied forces, the maximum unit shearing stress is $s_{s\,\max.} = {}^1/_2\,(s_1 - s_2)$. It acts along each of the two planes that make an angle of 45° with the planes normal to the direction of the applied forces.

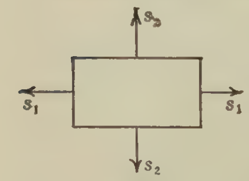

FIG. 12

**TENSILE OR COMPRESSIVE STRESS DUE TO SHEAR.**—In a body subjected to shear (e.g., a, bar in torsion) the balancing couples $s_s d$ and $s'_s d$ act on a particle of unit dimensions, Fig. 11. Since, for equilibrium, the two couples must be equal, $s_s = s'_s$. These stresses will result in a maximum tensile force, $P_t = \sqrt{2s_s^2}$, normal to the plane

$AC$ and perpendicular to the paper, and a maximum unit tensile stress normal to this plane, $s_t = \sqrt{2\,s_s^2}/\sqrt{2} = s_s$. Similarly, normal to the plane through $BD$ and perpendicular to the paper, there is a maximum unit compressive stress $s_c = s_s$. These stresses are particularly important in brittle materials, which when subjected to torsion, usually fail in tension with a helical fracture.

**DEFORMATION DUE TO NORMAL STRESSES AT RIGHT ANGLES.**—Let $s_1$ and $s_2$ be unit tensile stresses, acting on an element, at 90 deg. to each other, as shown in Fig. 12. Let $\lambda$ = Poisson's ratio, and $E$ = modulus of elasticity. The two stresses will produce unit elongations of $\epsilon_1 = s_1/E$ and $\epsilon_2 = s_2/E$, respectively, in the direction of the stresses. They will produce at the same time unit lateral contractions of $\lambda\epsilon_1$, and $\lambda\epsilon_2$, respectively, in directions at right angles to the stresses. The resultant unit elongation in the direction of $s_1$ will be $\epsilon_1 - \lambda\epsilon_2$; in the direction of $s_2$ it will be $\epsilon_2 - \lambda\epsilon_1$. If stress $s_2$ were compression and stress $s_1$ tension, the resultant elongation in the direction of $s_1$ would be $\epsilon_1 + \lambda\epsilon_2$; resultant contraction in the direction of $s_2$ would be $\epsilon_2 + \lambda\epsilon_1$.

Hence, the resultant deformation is reduced if both stresses are alike, and increased if the stresses are unlike. By experiment, $s = \epsilon E$, and for a uniaxial stress this accords with the definition that $s = P/A$; but if the resultant unit deformation due to biaxial loading is multiplied by $E$, the resulting unit stress in the direction of either applied load will not be the same as that obtained by $s = P/A$. The liability of the member to fail thus may be measured by the stress based on the external loads or by the deformation of the material. If both stresses are tension or compression, it is on the side of safety to neglect the effect of the lateral stresses and to use the stress based on the external loads, or $s = P/A$. If the lateral stresses are of opposite sign from the longitudinal stresses, and increase the longitudinal deformation, the effect of increased deformation may need to be considered. See Seely, Resistance of Materials, 2nd Ed. (John Wiley & Sons), pp. 234–239.

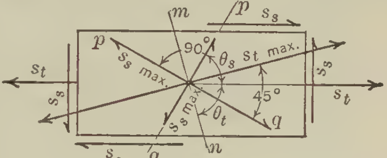

FIG. 13

**COMBINED TENSION OR COMPRESSION AND SHEAR.**—A particle subjected to tensile or compressive, as well as shearing stresses, will contain a plane $mn$, normal to which the unit tensile or compressive stress will be a maximum, and two planes, each at an angle of 45 deg. to $mn$, on which the shearing stress will be a maximum. In Fig. 13, the particle is subjected to a unit shearing stress of $s_s$, and a unit tensile stress of $s_t$, normal to plane $mn$. Then

$$s_{t\,\text{max.}} = (s_t/2) + \sqrt{s_s^2 + (s_t/2)^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad [8]$$

The plane $mn$ is at an angle $\theta_t$ with the direction $s_t$, and $\tan 2\theta_t = -\,2s_s/s_t$. With the same combination of stresses, the maximum unit compressive or minimum unit tensile stress, at 90 deg. to $s_{t\,\text{max.}}$, is

$$s_{t\,\text{min.}} = s_{c\,\text{max.}} = (s_t/2) - \sqrt{s_s^2 + (s_t/2)^2} \quad . \quad . \quad . \quad . \quad . \quad . \qquad [9]$$

The maximum unit shearing stress under this combination of stresses is

$$s_{s\,\text{max.}} = \sqrt{s_s^2 + (s_t/2)^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad [10]$$

and the angle $\theta_s$ of the two planes $pq$, 90 deg. apart, on which the stress acts, is given by $\tan 2\theta_s = s_t/(2s_s)$.

If the stresses are shear and compression, Fig. 14, maximum unit compressive stress is

$$s_{c\,\text{max.}} = (s_c/2) + \sqrt{s_s^2 + (s_c/2)^2} \quad . \quad . \qquad [11]$$

The angle $\theta_c$ of the plane to which the maximum unit compressive stress is normal is given by $\tan 2\theta_c = 2\,s_s/s_c$. Maximum unit shearing stress is

$$s_{s\,\text{max.}} = \sqrt{s_s^2 + (s_c/2)^2} \quad . \quad . \quad . \qquad [12]$$

and the angle $\theta_s$ of the plane on which it acts is given by $\tan 2\theta_s = -\,s_c/(2\,s_s)$. Maximum unit tensile stress for this combination of stresses is

$$s_{t\,\text{max.}} = s_{c\,\text{min.}} = (s_c/2) - \sqrt{s_s^2 + (s_c/2)^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad [13]$$

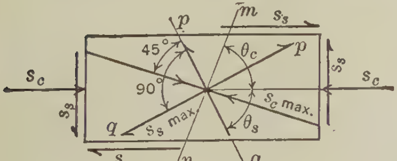

FIG. 14

**EFFECT OF NOTCHES AND HOLES IN MEMBERS UNDER SIMPLE STRESS.**—Formula $s = P/A$ assumes that the stress is uniformly distributed over the cross-section of the member. This is not true if there is any discontinuity in the cross-section, as an increase or decrease in area. In Fig. 15*a*, a plate of width $b$ having a small hole of radius $r$, is subjected to an axial pull $P$. The unit stress $s_1$, at any distance $x$ from the center line, is given by the formula (Timoshenko and Lessells, Applied Elasticity, p. 9),

$$s_1 = (s/2)\{2 + (r^2/x^2) + 3(r^4/x^4)\}. \qquad [14]$$

where $s$ = unit stress, based on the load $P$ and the area $A$, using the full width $b$. Where radius $r$ does not exceed $b/12$, stress $s_1 = 3s$.

For an elliptical hole of major axis $2a$ and minor axis $2b$, Fig. 15*b*, the maximum unit stress is $s_1 = s(1 + 2a/b)$. Notches of small radius on opposite sides of a tension specimen produce stresses approximately twice as great as the average stress; an example of this is the common briquette used in testing cement, in which the maximum tensile unit stress at the sides is 1.75 times average stress (Coker, *Proc.* Inter. Soc. Test. Mat., 1913).

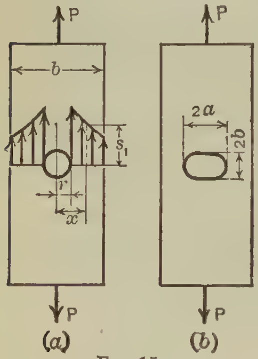

Fig. 15

**STRESS DUE TO TEMPERATURE.**—Let $l$ = length of a bar; $A$ = its sectional area; $c$ = coefficient of linear expansion for one degree, $t$ = rise or fall in temperature, deg.; $E$ = modulus of elasticity; $\lambda$ = change of length due to the rise or fall $t$; if the bar is free to expand or contract, $\lambda = ctl$.

If the bar is held so as to prevent its expansion or contraction, the stress produced by the change of temperature $= S = ActE$. The following are average values of the coefficients of linear expansion for a change in temperature of one degree Fahrenheit:

| | |
|---|---|
| For brick and stone | $c = 0.0000050$ |
| For cast iron | $c = 0.0000056$ |
| For wrought iron and steel | $c = 0.0000065$ |

The stress due to temperature should be added to or subtracted from the stress caused by other external forces, according as it acts to increase or to relieve the existing stress.

Example.—Compute the stress caused in a steel bar 1 in. square in area, by a change of temperature of 100° F. *Solution.*— $S = ActE = 1 \times 0.0000065 \times 100 \times 30{,}000{,}000 = 19{,}500$ lb. Suppose the bar is under tension of 19,500 lb. between rigid abutments before the change in temperature takes place, a cooling of 100° F. will double the tension, and a heating of 100° will reduce the tension to zero.

## 4. ALLOWABLE STRESS AND FACTOR OF SAFETY

**ALLOWABLE UNIT STRESS,** also called allowable working unit stress, allowable stress, or working stress, is the maximum unit stress to which it is considered safe to subject a member in service. The term allowable stress is preferable to working stress, since the latter often is used to indicate the actual stress in a material when in service. Allowable unit stresses for different materials for various conditions of service are specified by different authorities on the basis of test or experience. In general, for ductile materials, allowable stress is considerably less than the yield point.

**FACTOR OF SAFETY** is the ratio of ultimate strength of the material to allowable stress. The term was originated for determining allowable stress. The ultimate strength of a given material divided by an arbitrary factor of safety, dependent on material and the use to which it is to be put, gives the allowable stress. In present design practice, it is customary to use allowable stress as specified by recognized authorities or building codes rather than an arbitrary factor of safety. One reason for this is that the factor of safety is misleading, in that it implies a greater degree of safety than actually exists. For example, a factor of safety of 4 does not mean that a member can carry a load four times as great as that for which it was designed. It also should be clearly understood that, even though each part of a machine is designed with the same factor of safety, the machine as a whole does not have that factor of safety. When one part is stressed beyond the proportional limit, or particularly the yield point, the load or stress distribution may be completely changed throughout the entire machine or structure, and its ability to function thus may be changed, even though no part has ruptured.

While no definite rules can be given, if a factor of safety is to be used, the following circumstances should be taken into account in its selection:

1. When the ultimate strength of the material is known within narrow limits as for structural steel for which tests of samples have been made, when the load is entirely a steady one of a known amount and there is no reason to fear the deterioration of the metal by corrosion, the lowest factor that should be adopted is 3.

2. When the circumstances of 1 are modified by a portion of the load being variable, as in floors of warehouses, the factor should be not less than 4.

3. When the whole load, or nearly the whole, is apt to be alternately put on and taken off, as in suspension rods of floors of bridges, the factor should be 5 or 6.

4. When the stresses are reversed in direction from tension to compression, as in some bridge diagonals and parts of machines, the factor should be not less than 6.

5. When the piece is subjected to repeated shocks, the factor should be not less than 10.

6. When the piece is subjected to deterioration from corrosion the section should be sufficiently increased to allow for a definite amount of corrosion before the piece will be so far weakened by it as to require removal.

7. When the strength of the material or the amount of the load or both are uncertain, the factor should be increased by an allowance sufficient to cover the amount of the uncertainty.

8. When the strains are of a complex character and of uncertain amount, such as those in the crank-shaft of a reversing engine, a very high factor is necessary, possibly even as high as 40.

9. If the property loss caused by failure of the part may be large or if loss of life may result, as in a derrick hoisting materials over a crowded street, the factor should be large.

Table 2, from Merriman, Mechanics of Materials, gives average values of factors of safety for different conditions. The factors given by different authorities for some materials show wide differences.

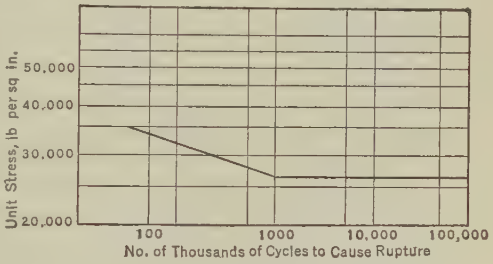

Fig. 16. Endurance Stress Curve

## 5. REPEATED STRESS

**PARTS SUBJECTED TO REPEATED STRESS.**—Where parts of a structure or machine are subjected to varying or repeated loads, the ordinary methods of computing stresses and of determining the strength of materials under static load conditions are not satisfactory. In general, in excess of one-half to ten million repetitions of loading are necessary before the parts come under this classification. Such parts are crank-shafts, shafts carrying rotating parts, as in motors and generators, turbine blades, valve parts, piston rods in steam engines, floor beams in elevated railroads, etc.

**CHARACTER OF FAILURE.**—Under repeated loadings, failures take place suddenly and without warning. The mechanism of *fatigue failure* under repeated stress appears to be that exceedingly small particles of metal are stressed beyond the elastic limit. As the stress is repeated, a tiny crack, sometimes called a *fatigue crack*, is formed and progresses until failure occurs. This action is referred to as a *progressive failure.* Therefore, where the load is repeated, anything which causes a concentration of stress is a source of weakness.

**DETERMINATION OF ENDURANCE LIMIT.**—The highest unit stress $s$ at which a material can be subjected to a very large number of repetitions of loading $N$ without evidence of failure, is the *endurance limit.* This usually is found for any given metal by constructing an $s$-$N$ diagram for that particular metal, from data obtained by tests. A piece of metal is so loaded as to produce a given stress, the load being repeated until failure occurs. Other specimens then are tested at different values of the unit stress, until enough points have been obtained to plot a curve. This curve will incline steeply at the higher stresses and gradually flatten out at the lower stresses until it approaches a horizontal line. The unit stress at which the curve becomes horizontal is the endurance limit. See Fig. 16. The most common test is that of reversed bending by the rotating beam method, since this specimen is the most easily made and the testing machines are the least costly. Tests also are made in direct tension, direct shear, direct compression, reversed torsion, and in various combination of these.

**Table 2.—Average Values of Factor of Safety**

| Material | Steady stress | Variable stress | Shocks | Material | Steady stress | Variable stress | Shocks |
|---|---|---|---|---|---|---|---|
| Cast iron.......... | 6 | 10 | 20 | Hard steel......... | 5 | 8 | 15 |
| Wrought iron...... | 4 | 6 | 10 | Timber............ | 8 | 10 | 15 |
| Structural steel..... | 4 | 6 | 10 | Brick and stone.... | 15 | 25 | 40 |

**VALUES OF ENDURANCE LIMIT.**—Moore and Kommers, and Moore and Jasper (*Bull.* 124 and 126, Engg. Exp. Sta., Univ. of Ill., 1921, 1923) reach a number of conclusions concerning wrought ferrous metals. A summary of the more important of these follows:

1. It is considered as well established that for wrought ferrous metals there is an endurance limit stress below which they will withstand an indefinite number of repetitions of stress.
2. In reversed bending, a fairly definite relation exists between the endurance limit, the ultimate tensile strength, and the Brinell hardness number. The endurance limit is about 50% of the ultimate tensile strength, with values ranging between 40% and 60%. The endurance limit is between 200 and 250 times the Brinell hardness number.
3. No relation exists between endurance limit and impact test or repeated-impact test results.
4. The endurance limit in reversed torsion (shear) varies from 48 to 60% of the endurance limit in reversed bending.
5. The endurance limit in reversed axial stress (tension to compression) varies from 56 to 70% of the endurance limit under reversed bending with nearly all the values 60% or above. The reason for this low value is that practically all axial loads are slightly eccentric and cause bending. Irwin (*Proc.* A.S.T.M., vol. xxv, Pt. II, p. 53, 1925), with a specially designed machine, found the reversed axial stress to be practically the same as that in reversed bending.

A report of Research Committee on Fatigue of Metals (*Proc.* A.S.T.M., vol. xxx, Pt. I, p. 259, 1930) gives a concise statement of the state of knowledge at that date, which corroborates the above conclusions with the following changes or additions:

1. No general relation exists between yield point or proportional limit and endurance limit.
2. For cast ferrous metals the endurance limit is about 40% of the tensile strength.
3. For non-ferrous metals no definite relation exists between endurance limit and tensile strength, the values varying between 18 and 50%.
4. For cast ferrous metals endurance limit is about 26% of the modulus of rupture.
5. For wrought ferrous metals the endurance limit is about 250 times the Brinell number for numbers under 400. For Brinell numbers exceeding 400, the relation does not hold. For cast ferrous metals and for non-ferrous metals sufficient data are not available to permit judging the degree of correlation.

Table 3 gives the endurance limit and other properties of a number of ferrous metals. Table 6 gives similar information for non-ferrous metals. The values of the endurance limit for heat-treated steels vary according to the treatment, ranging from 29,300 to 68,000 lb. per sq. in. for a 0.49% carbon steel, from 50,000 to 108,000 lb. per sq. in. for a

| Axial tension to axial compression | 24–40* | ...... | ...... |

* With precise loading devices this value has been found to be practically the same as in reversed bending, but such refinement in loading cannot be obtained in practice.

1.20% carbon steel, and from 54,000 to 120,000 lb. per sq. in. for a 3.50% nickel steel.

Table 5 summarizes the endurance ratios (ratio of ultimate tensile strength to endurance limit) for different types of stress. Moore and Kommers (Fatigue of Metals, McGraw-Hill, 1927, p. 147) state that the ratio of endurance limits in reversed torsion and reversed bending averages: Plain carbon steels, 0.55; alloy steels, 0.58; non-ferrous metals, 0.52.

**EFFECT OF SCRATCHES AND DEFECTS ON ENDURANCE LIMIT OF ROLLED OR FORGED FERROUS METALS.**—The beginning of rupture under repeated stress is supposed to be at a point of discontinuity in the material. The same principle applies to a discontinuity on the outer surface where, in bending or torsion, the stress is greatest. The presence of scratches, sharp corners, or grooves reduces the endurance limit an appreciable amount. Moore and Kommers (*Bull.* Engg. Exp. Sta., Univ. of Ill., No. 124) obtained the following reductions in the endurance limit, using steel of 0.02% C and 0.49% C, with results the same for each steel. The experiments were made on bars 0.40 in. diam., turned down to 0.275 in. diam. at bottom of the notch.

Surface finish has an appreciable effect on endurance limit. The standard finish used in the experiments of Moore and Kommers was obtained by polishing a smooth turned specimen with No. 0 and 00 emery cloth. Unpolished smooth-turned specimens had an endurance limit 8 to 12% lower than those that were polished; a rough-turned finish gave a slightly lower value than the smooth-turned finish. For cast-iron specimens having a 60° groove with a bottom radius of 5/64 in., the reduction in the endurance limit was only 8%. The effect of scratches, grooves, and external discontinuities is not so great in cast iron as in steel.

According to the theory of elasticity, a small hole, of diameter less than 1/6 the diameter of the specimen, should cause a stress at the edge of the hole three times the stress based on a uniform stress distribution, and therefore should reduce the endurance limit to 33% of that which would be obtained on a solid specimen. Tests on rotating beams of various steels with a small hole drilled through a diameter gave endurance limits from 50 to 65% of those for the solid beams, showing that theoretically high stresses do not produce corresponding failures, probably due to readjustments in the ductile metal.

**EFFECT OF RANGE OF STRESS.**—The endurance limit as determined by a rotating beam is the endurance limit for a complete reversal of stress from tension to compression, and *vice versa.* The endurance limit is less for a complete reversal than it is for those stress combinations where the stress goes only from a maximum to zero, or from a maximum to a minimum which is above zero. Howell (*Bull.* 136, Engg. Exp Sta., Univ. of Ill.), proposed the empirical relation $s = s_1(r + 3)/2$, where $s$ = endurance limit for the range of stress $r$; $s_1$ = endurance limit for completely reversed stress of the same character as $s$, *i.e.*, direct stress, bending, torsion, etc.; $r$ = ratio of the minimum stress to the maximum stress for a cycle of stress; for instance, if stress varies from 6000 lb. per sq. in. compression to 10,000 lb. per sq. in. tension, the ratio $r$ would be $-6000/+10{,}000 = 0.60$. Using the above notation, a formula was suggested by Moore, Kommers and Jasper (*Proc.* A.S.T.M., vol. xxii, Pt. II, 1922) where $s = 3s_1/(2 - r)$. This gives values for forged or rolled iron and steel which accord fairly well with tests, being on the safe side. For a complete digest of data, see Report of Research Committee on Fatigue of Metals, *Proc.* A.S.T.M., vol. xxx, Pt. I, p. 259, 1930.

**EFFECT OF CORROSION.**—If a part is subjected to repeated loads and at the same time to corrosive agencies, the endurance limit may be greatly reduced from its normal value as determined in air. McAdam at the U. S. Naval Engg. Exp. Sta., Annapolis (*Proc.*, A.S.T.M., vol. xxvi, Pt. II, p. 224, 1926, the first of many papers), has experimented on various steels with a number of corrosive agents. He found that the endurance limit may be reduced to one-third its normal value. Even so mild an agent as a stream of fresh water may reduce the endurance limit one-half, and salt water or water containing other salts in solution is very destructive. Practically all steels are affected, the corrosion-resistant ones less so than ordinary steels. Steam at 220 lb. per sq. in., and 700° F., without appreciable amounts of oxygen or liquid water did not greatly affect chromium-iron or nickel-steels, but when these steels were tested in air under a jet of steam, their strengths were reduced (Fuller, *Tech Pub.* No. 294, A.I.M. & M.E., and *Met. Prog.*, July, 1931, p. 79).

In *corrosion-fatigue*, the stress need not be high enough to have started fatigue cracks without corrosion. The protective film of oxide breaks down under alternating stress and allows the formation of corrosion pits which progress more rapidly under stress than without it. The pits cause a high concentration of stress at the bottom, and this cycle of the pit increasing the stress and the stress increasing the depth of the pit continues; when the stress has been raised beyond the endurance limit, a fatigue crack starts. It has not yet (1937) been possible to obtain "corrosion-fatigue" values which can be used directly in design.

The most effective method of protection is to keep from contact with corrosive agents, the parts subjected to repeated loads. Where this is not possible, a protective coating of some elastic material, such as varnish, cement, or enamel, will aid. Certain substances called inhibitors, such as sodium chromate, introduced into the corrosive stream or applied in some other way, have been found to help in restoring the protective film.

## 6. ENERGY OR DYNAMIC LOADS

**CLASSIFICATION OF LOADS.**—A **Static Load** is one that increases gradually from zero to its full intensity; its effect on a bar has been considered above.

A **Suddenly Applied Load** is one that is released at the instant of contact with the bar, and then acts at its full intensity from the beginning to the end of the deformation.

A **Moving Load,** is one that is moving when it is brought to bear on the bar. The effect of such a load which is denoted by the word *impact*, is much greater than that of a static or a suddenly applied load.

Suddenly applied and moving loads often are termed *dynamic loads* or *energy loads.*

**RELATION BETWEEN STORED ENERGY AND SIZE OF MEMBER.**—The external work (see p. 7–07) performed in deforming a bar within the proportional limit is $1/_2\, s^2\, Al/E$, where $s$ = unit stress; $A$ = cross-sectional area of bar; $l$ = length of bar; $E$ = modulus of elasticity. This also is the energy stored in the bar. Since the energy absorbed varies directly as the square of the unit stress, it follows that large amounts of energy will be absorbed by those portions where the stress is high. It is important that where high stresses occur they should be present over as great a length of the member as possible. If one part of the rod must be of small diameter, it is advisable that as great a length of the rod as possible be of same small diameter; otherwise the high concentration of energy in a small portion of the member may cause failure. See Seely, Resistance of Materials, 2nd Ed., p. 271.

**EFFECT OF SUDDEN LOADS.**—If a sudden load $P$ be applied to a bar, it will cause deformation $\epsilon l$, and the work done by the load will be $P\epsilon l$. Since the external work equals the internal work, $P\epsilon l = s^2Al/2E$, and since $\epsilon = s/E$, $P = sA/2$, or $s = 2P/A$. The unit stress, and also the unit deformation, is double that under an equal load applied gradually. However, the bar does not maintain equilibrium at the point of maximum stress and deformation, but, after a series of oscillations in which the surplus energy is dissipated in heat, it finally comes to rest with the same deformation and stress as that due to the equal static load.

**STRESS DUE TO LIVE LOADS.**—In structural design two loads are considered, the dead load or weight of the structure and the live load or superimposed loads to be carried. The stresses due to the dead load and to the live loads respectively are computed separately, regarding each as a static load. It is obvious that the stress due to the live load may be greatly increased, depending on the suddenness with which the load is applied. It has been shown above that the stress due to a suddenly applied load is double the stress caused by a static load. The term *coefficient of impact* is used extensively in structural engineering to denote the number by which the computed static stress is multiplied to obtain the value of the increased stress assumed to be caused by the suddenness of application of the live load. If $s$ = static unit stress computed from the live load, and $i$ = coefficient of impact, then the increase of unit stress due to sudden loading is $is$, and the total unit stress due to the live load is $s + is$. The value of $i$ has been determined by empirical methods and varies according to different conditions. In the building codes of most cities, specified floor loads for buildings include the impact allowance, and no increase is needed for live loads except for special cases of vibration or other unusual conditions. For railroad bridges, the value of $i$ depends upon the proportion of the length of the bridge which is loaded. No increase in the static stress is needed when the mass of the structure, as in monolithic concrete, is great. For machinery and for unusual conditions, such as elevator machinery and its supports, each structure should be considered by itself and the coefficient assumed accordingly. It should be noted that the meaning of the word impact used above differs somewhat from its strict theoretical meaning and as it is used in the next paragraph. The use of the terms impact and coefficient of impact in connection with live load stresses is, however, very general.

**AXIAL IMPACT ON BARS.**—A load $P$ dropped from a height $h$ on to the end of a vertical bar of cross-sectional area $A$, rigidly secured at the bottom end, produces in the bar a unit stress which increases from 0 up to $s'$, with a corresponding total deformation increasing from 0 up to $e_1$. The work done on the bar is $P\,(h + e_1)$ which, provided no energy is expended as heat or in giving velocity to the bar, is equal to the energy $1/_2\, s'\, Ae_1$ stored in the bar; that is,

$$P\,(h + e_1) = 1/_2\, s'\, Ae_1 \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad [15]$$

If $e$ = deformation produced by a static load $P$, then within the proportional limit

$$e_1/e = s'/(P/A) \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad [16]$$

Combining this with equation [15] gives

$$s' = s + s\sqrt{1 + (2\,h/e)} \quad . \; . \; . \quad [17]; \qquad e_1 = e + e\sqrt{1 + (2\,h/e)} \quad . \; . \quad [18]$$

A wrought-iron bar 1 in. square and 5 ft. long, under a static load of 5000 lb., will be shortened about 0.012 in., assuming no lateral flexure to occur; but, if a weight of 5000 lb. drops on its end from a height of 0.048 in., a stress of 20,000 lb. will be produced.

Formulas [17] and [18] give values of stress and deformation that are somewhat large, because part of the energy of the applied force is not effective in producing stress, but is expended in overcoming the inertia of the bar and in producing local stresses. For light bars, they give approximately correct results.

If the bar is horizontal and is struck at one end by a weight $P$, moving with a velocity $V$, the deformation produced is $e_1$. Then, as before, $\frac{1}{2} s' A e_1 = Ph$. In this case $h = V^2/2g$ = height from which $P$ would have to fall to acquire velocity $V$. $g$ = acceleration due to gravity = 32.16 ft. per sec. per sec. Combining with equation [16],

$$s' = s\sqrt{(2h/e)} \quad . \quad . \quad . \quad . \quad . \quad [19]; \qquad e_1 = e\sqrt{(2h/e)} \quad . \quad . \quad . \quad . \quad . \quad [20]$$

**IMPACT ON BEAMS.**—If a weight $P$ falls on a horizontal beam from a height $h$, producing a maximum deflection $y_1$ and a maximum unit stress $s'$ in the extreme fiber, the values of $s'$ and $y_1$ are given by

$$s' = s + s\sqrt{1 + 2h/y} \quad . \quad . \quad [21]; \qquad y_1 = y + y\sqrt{1 + 2h/y} \quad . \quad . \quad [22]$$

where $s$ = extreme fiber unit stress; $y$ = deflection due to $P$, considered as a static load. The value of $s$ may be obtained from the flexure formula (p. 7–19); that of $y$ from the proper formula for deflection under static load.

If a weight $P$ moving horizontally with a velocity $V$ strikes a beam, the ends of which are secured against horizontal movement, the maximum fiber unit stress and the maximum lateral deflection are given by

$$s' = s\sqrt{2h/y} \quad . \quad . \quad . \quad . \quad . \quad [23]; \qquad y_1 = y\sqrt{2h/y} \quad . \quad . \quad . \quad . \quad . \quad [24]$$

where $s$ and $y$ are as before, and $h$ is height through which $P$ would have to fall to acquire the velocity $V$. These formulas, like those for axial impact on bars, give results larger than those observed in tests, particularly if the weight of the beam is great. For further discussion, see Seely's Resistance of Materials, 2nd Ed., Chapter 11.

**RUPTURE FROM IMPACT.**—Rupture may be caused by impact provided the load has the requisite velocity. The above formulas, however, do not apply since they are valid only for stresses within the proportional limit. The only information available has been obtained through experiment. Hatt has determined from nearly 200 experiments that the work required for rupture from impact was about 30% greater than that required by static loads. From available test data, it does not seem that the ultimate elongation under impact (dynamic) loads is widely different from that under static loads. For the results of a large number of impact tests on cast iron, see *Proc.* A.S.T.M., vol. xxxiii, Pt. I, p. 87, 1933.

# BEAMS

## 1. THEORY OF FLEXURE

**TYPES OF BEAMS.**—A beam is a bar or structural member subjected to transverse loads that tend to bend it. Any structural member acts as a beam if bending is induced by external transverse forces.

**A Simple Beam** (Fig. 1*a*) is a horizontal member that rests on two supports at the ends of the beam. All parts between the supports have free movement in a vertical plane under the influence of vertical loads.

**A Fixed Beam, Constrained Beam, or Restrained Beam** (Fig. 1*b*) is one that is rigidly fixed at both ends or rigidly fixed at one end and simply supported at the other.

**A Continuous Beam** (Fig. 1*c*) is a member resting on more than two supports.

**A Cantilever Beam** (Fig. 1*d*) is a member with one end projecting beyond the point of support, free to move in a vertical plane under the influence of vertical loads placed between the free end and the support.

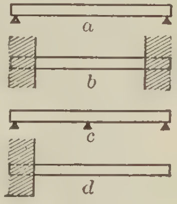

Fig. 1

**PHENOMENA OF FLEXURE.**—When a simple beam bends under its own weight, the fibers on the upper or concave side are shortened, and the stress acting on them is compression; the fibers on the under or convex side are lengthened and the stress acting on them is tension. In addition, shear exists along each cross-section, the intensity of which is greatest along the sections at the two supports and zero at the middle section.

When a cantilever beam bends under its own weight the fibers on the upper or convex side are lengthened under tensile stresses; the fibers on the under or concave side are shortened under compressive stresses; the shear is greatest along the section at the support, and zero at the free end.

**THE NEUTRAL SURFACE** is that horizontal section between the concave and convex surfaces of a loaded beam, where there is no change in the length of the fibers and no tensile or compressive stresses acting upon them.

**THE NEUTRAL AXIS** is the trace of the neutral surface on any cross-section of a beam. See Fig. 2.

**THE ELASTIC CURVE** of a beam is the curve formed by the intersection of the neutral surface with the side of the beam, it being assumed that the longitudinal stresses on the fibers are within the elastic limit.

**REACTIONS AT SUPPORTS.**—The reactions, or upward pressures at the points of support, are computed by applying the following conditions necessary for equilibrium of a system of vertical forces in the same plane: 1. The algebraic sum of all vertical forces must equal zero; *i.e.*, the sum of the reactions equals the sum of the downward loads. 2. The algebraic sum of the moments of all the vertical forces must equal zero. Condition 1 applies to cantilever beams, and to simple beams uniformly loaded, or with equal concentrated loads placed at equal distances from the center of the beam. In the cantilever beam, the reaction is the sum of all the vertical forces acting downward, comprising the weight of the beam and the superposed loads. In the simple beam each reaction is equal to one-half the total load, consisting of the weight of the beam and the superposed loads. Condition 2 applies to a simple beam not uniformly loaded. The reactions are computed separately, by determining the moment of the several loads about each support. The sum of the moments of the load around one support is equal to the moment of the reaction of the other support around the first support.

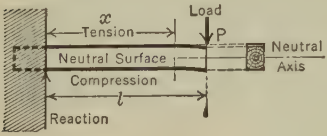

FIG. 2

EXAMPLE.—Determine reactions $R_1$, $R_2$ of a simple beam 20 ft. long, loaded as in Fig. 3. The weight of the beam may be taken as a concentrated load applied at the center of gravity of the beam. Then, moments around left-hand and right-hand supports are, respectively,

Left-hand, $(2000 \times 5) + (3000 \times 9) + (1200 \times 10) - (R_2 \times 20) = 0$; $R_2 = 2450$ lb.
Right-hand, $(R_1 \times 20) - (2000 \times 15) - (3000 \times 11) - (1200 \times 10) = 0$; $R_1 = 3750$ lb.
$R_1 + R_2 = 6200$ lb. = sum of all loads acting downward.

**CONDITIONS OF EQUILIBRIUM.**—The fundamental laws for the stresses at any cross-section of a beam in equilibrium are:

1. Sum of horizontal tensile stresses = sum of horizontal compressive stresses. 2. Resisting shear = vertical shear. 3. Resisting moment = bending moment.

**Vertical Shear.**—At any cross-section of a beam the resultant of the external vertical forces acting on one side of the section is equal and opposite to the resultant of the external vertical forces on the other side of the section. These forces tend to cause the beam to shear vertically along the section. The value of either resultant is known as the vertical shear at the section considered. It is computed by finding the algebraic sum of the vertical forces to the left of the section; that is, it is equal to the left reaction minus the sum of the vertical downward forces acting between the left support and the section.

**A Shear Diagram** is a graphic representation of the vertical shear at all cross-sections of the beam. Thus in the simple beam, Fig. 4, the ordinates to the line *AOB* represent to scale the intensity of the vertical shear at the corresponding sections of the beam. The vertical shear is greatest at the supports, where it is equal to the reactions, and it is zero at the center of the span. In the cantilever beam, Fig. 5, the vertical shear is greatest at the point of support where it is equal to the reaction, and it is zero at the free end. Fig. 6 shows graphically the vertical shear on all sections of a simple beam carrying two concentrated loads at equal distances from the supports, the weight of the beam being neglected.

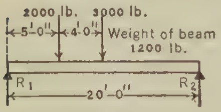

FIG. 3

**Resisting Shear.**—The tendency of a beam to shear vertically along any cross-section, due to the vertical shear, is opposed by an internal shearing stress at that cross-section known as the resisting shear; it is equal to the algebraic sum of the vertical components of all the internal stresses acting on the cross-section.

If $V$ = vertical shear, lb.; $V_r$ = resisting shear, lb.; $s_s$ = average unit shearing stress, lb. per sq. in.; and $A$ = area of the section, sq. in., then at any cross-section

$$V_r = V = s_sA;\ s_s = V/A \qquad [1]$$

The resisting shear is not uniformly distributed over the cross-section, but the intensity varies from zero at the extreme fiber to its maximum value at the neutral axis.

At any point in any cross-section the vertical unit shearing stress, lb. per sq. in., is

$$s_s = VA'c'/It \qquad [2]$$

where $V$ = total vertical shear, lb., for section considered; $A'$ = area, sq. in., of cross-section between a horizontal plane through point where shear is being found and the extreme fiber on the same side of the neutral axis; $c'$ = distance, in., from neutral axis to center of gravity of area $A'$; $I$ = moment of inertia of the section, in.$^4$; $t$ = width of section at plane of shear, in. Maximum value of the unit shearing stress, where $A$ = total area, sq. in., of cross-section of the beam, is

For a solid rectangular beam, $s_s = 3V/2A$ . . . . . . . . . . . . [3]

For a solid circular beam, $s_s = 4V/3A$ . . . . . . . . . . . . [4]

**Horizontal Shear.**—In a beam, at any cross-section where there is a vertical shearing force, there must be resultant unit shearing stresses acting on the vertical faces of particles which lie at that section. On a horizontal surface of such a particle, there is a unit shearing stress equal to the unit shearing stress on a vertical surface of the particle. Equation [2] therefore also gives the horizontal unit shearing stress at any point on the cross-section of a beam.

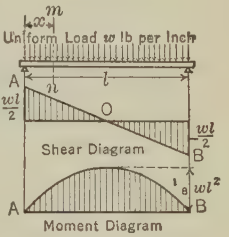

FIG. 4. Shear Diagram, Simple Beam

**Bending Moment,** at any cross-section of a beam, is the algebraic sum of the moments of the external forces acting on either side of the section. It is positive when it causes the beam to bend convex downward, hence causing compression in upper fibers and tension in lower fibers of beam. When the bending moment is determined from the forces that lie to the left of the section, it is positive if it acts in a clockwise direction; if determined from forces on the right side, it is positive if it acts in a counter-clockwise direction. If the moments of upward forces are given positive signs, and the moments of downward forces negative signs, the bending moment always will have the correct sign, whether determined from the right or left side. The bending moment should be determined for the side for which the calculation will be simplest.

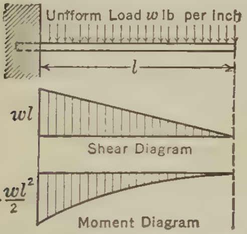

FIG. 5. Shear Diagram, Cantilever Beam

In Fig. 4 let $M$ be the bending moment, lb.-in., at a section $mn$ of a simple beam at a distance $x$, in. from the left support; $w$ = weight of beam per 1 in. of length; $l$ = length of the beam, in. Then the reactions are $\frac{1}{2}wl$, and $M = \frac{1}{2}wlx - \frac{1}{2}xwx$. For the sections at the supports, $x = 0$ or $l$ and $M = 0$. For the section at the center of the span $x = \frac{1}{2}l$ and $M = \frac{1}{8}wl^2 = \frac{1}{8}Wl$, where $W$ = total weight.

**A Moment Diagram** (Figs. 4, 5, and 6) shows the bending moment at all cross-sections of a beam. Ordinates to the curve represent to scale the moments at the corresponding cross-sections. The curve for a simple beam uniformly loaded is a parabola, showing $M = 0$ at the supports and $M = \frac{1}{8}wl^2 = \frac{1}{8}Wl$ at the center, $M$ being in lb.-in.

**The Dangerous Section** is the cross-section of a beam where the bending moment is greatest. In a cantilever beam it is at the point of support, regardless of the disposition of the loads. In a simple beam it is that section where the vertical shear changes from positive to negative, and may be located graphically by constructing a shear diagram, or numerically by taking the left reaction and subtracting the loads in order from the left until a point is reached where the sum of the loads subtracted equals the reaction. For a simple beam, uniformly loaded, the dangerous section is at the center of the span.

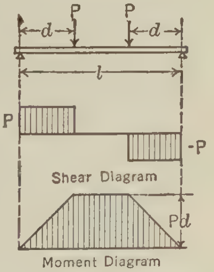

FIG. 6. Shear Diagram, Beam with Two Concentrated Loads

**Resisting Moment.**—The tendency to rotate about a point in any cross-section of a beam is due to the bending moment at that section; this tendency is resisted by the resisting moment which is the algebraic sum of the moments of all the horizontal stresses with reference to the same point.

**FORMULA FOR FLEXURE.**—Let $M$ = bending moment; $M_r$ = resisting moment of the horizontal fiber stresses; $s$ = unit stress (tensile or compressive) on any fiber, usually that one most remote from the neutral surface; $c$ = distance of that fiber from the neutral surface. Then

$M = M_r = sI/c$ . . . . [5]; $s = Mc/I$ . . . . . . . . . [6]

where $I$ = moment of inertia of the cross-section with respect to its neutral axis. If $s$ is in lb. per sq. in., then $M$ must be in lb.-in., $I$ in in.$^4$, and $c$ in in.

Formula [6] is the basis of the design and investigation of beams. It is true only when the maximum horizontal fiber stress $s$ does not exceed the proportional limit of the material.

### Table 1.—Elements of Sections

$A$ = area of section.

$I$ = moment of inertia about axis $I$–$I$.

$c$ = distance from axis $I$–$I$ to remotest point of section.

$I/c$ = section modulus.

$r$ = radius of gyration.

**MOMENT OF INERTIA** is the sum of the products of each elementary area of the cross-section multiplied by the square of the distance of that area from the assumed axis of rotation, or

$$I = \Sigma r^2\Delta A = \int r^2dA \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad [7]$$

where $\Sigma$ is the sign of summation, $\Delta A$ = an elementary area of the section, and $r$ = distance of $\Delta A$ from the axis. The moment of inertia is greatest in those sections (such as I-beams) having much of the area concentrated at a distance from the axis. Unless otherwise stated the neutral axis is the axis of rotation considered. $I$ usually is expressed in in.$^4$ See Table 1 for values of moments of inertia of various sections.

**MODULUS OF RUPTURE** is the term applied to the value of $s$ as found by formula [6], when a beam is loaded to the point of rupture. Since formula [6] is true only for stresses within the proportional limit, the value $s$ of the rupture strength so found is incorrect. However, the equation is used, as a measure of the ultimate load-carrying capacity of a beam. The modulus of rupture does not show the actual stress in the extreme fiber of a beam; it is useful only as a basis of comparison. If the strength of a beam in tension differs from its strength in compression, the modulus of rupture is intermediate between the two.

**SECTION MODULUS** is the factor $I/c$ in flexure formula [5], and is expressed in in.$^3$ It is the measure of a capacity of a section to resist a bending moment. For values of $I/c$ for simple shapes, see Table 1. See pp. 17–50 to 17–72 for properties of standard steel structural sections, and p. 6–12 for properties of aluminum sections.

**ELASTIC DEFLECTION OF BEAMS.**—When a beam bends under load, all points of the elastic curve except those over the supports are deflected from their original positions. The radius of curvature $\rho$ of the elastic curve at any section is expressed as

$$\rho = EI/M \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [8]$$

where $E$ = modulus of elasticity of the material, lb. per sq. in.; $I$ = moment of inertia, in.$^4$, of the cross-section with reference to its neutral axis; $M$ = bending moment, lb.-in., at the section considered. Where there is no bending moment, $\rho$ is infinity and the curve is a straight line; where $M$ is greatest, $\rho$ is smallest, and the curvature, therefore, is greatest.

If the elastic curve be referred to a system of co-ordinate axes in which $x$ represents horizontal distances, $y$ vertical distances, and $l$ distances along the curve, the value of $\rho$ is found, by the aid of the calculus, to be $d^3l/dx \cdot d^2y$. Substituting this value in the expression $\rho = EI/M$ and assuming that $dx$ and $dl$ are practically equal, there results differential equation [9] of the elastic curve which applies to all beams when the elastic limit of the material is not exceeded:

$$EI(d^2y/dx^2) = M \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [9]$$

Equation [9] is used to determine the deflection of any point of the elastic curve, by regarding the point of support as the origin of the co-ordinate axis, taking $y$ as the vertical deflection at any point on the curve and $x$ as the horizontal distance from the support to the point considered. The values of $E$, $I$, and $M$ are substituted and the expression is integrated twice, giving proper values to the constants of integration, and the deflection $y$ is determined for any point. See Table 2.

For example, the cantilever beam shown in Fig. 2 has a length = $l$, inches, and carries a load $P$, pounds, at the free end. It is required to find the deflection of the elastic curve at a point distant $x$, inches, from the support, the weight of the beam being neglected.

The moment $M = -P(l - x)$; substituting in [9], the equation for the elastic curve becomes $EI(d^2y/dx^2) = -Pl + Px$. Integrating and determining the constant of integration by the condition that $dy/dx = 0$ when $x = 0$, there results $EI(dy/dx) = -Plx + {}^1/_2\,Px^2$. Integrating a second time and determining the constant by the condition that $x = 0$ when $y = 0$, there results $EIy = -{}^1/_2\,Plx^2 + {}^1/_6\,Px^3$, which is the equation of the elastic curve. When $x = l$, the value of $y$, or the deflection in inches at the free end, is found to be $-Pl^3/3\,EI$.

**DEFLECTION DUE TO SHEAR.**—The deflection of a beam as computed by the ordinary formulas is that due to flexural stresses only. In short beams the deflection due to vertical shear sometimes is appreciable and may need to be considered. Because of the non-uniform distribution of the shear over the cross-section of the beam, computing the deflection due to shear by exact methods is difficult. It may be approximated by $y_s = M/AE_s$, where $y_s$ = deflection, in., due to shear; $M$ = bending moment, lb.-in., at the section where the deflection is calculated; $E_s$ = modulus of elasticity in shear, lb. per sq. in.; $A$ = area of cross-section of beam, sq. in. (see Seely's Resistance of Materials, 2nd Ed., p. 136). Swain says (Strength of Materials, McGraw-Hill Book Co., p. 223) that for a rectangular section, the ratio of deflection due to shear, to deflection due to bending, will be less than 5% if the depth of the beam is less than ${}^1/_8$ of the length.

## 2. BEAMS OF UNIFORM CROSS-SECTION

**DESIGN PROCEDURE.**—In designing a beam the procedure is: 1. Compute reactions. 2. Determine position of the dangerous section and the bending moment at that section. 3. Divide the maximum bending moment (expressed in lb.-in.) by the allowable unit stress (expressed in lb. per sq. in.) to obtain the minimum value of the section modulus. 4. Select a beam section with a section modulus equal to or slightly greater than the section modulus required.

**WEB SHEAR.**—A beam designed in the above manner is safe against rupture of the extreme fibers due to bending in a vertical plane, and usually the cross-section will have sufficient area to sustain the shearing stresses with safety. For short beams carrying heavy loads, however, the vertical shear at the supports is large, and it may be necessary to increase the area of the section to keep the unit shearing stress within the limit allowed. For steel beams, the average unit shearing stress is computed by $s_s = V/A$, where $V$ = total vertical shear, lb.; $A$ = area of web, sq. in. For allowable average unit shearing stresses in cross-section of web of girders and rolled steel beams, see p. 17–47. For timber beams, see Horizontal Shear in Timber Beams, p. 7–26.

**MISCELLANEOUS CONSIDERATIONS.**—Other considerations which will influence the choice of section under certain conditions of loading are: 1. Maximum vertical deflection that may be permitted in beams coming in contact with plaster. 2. Danger of failure by sidewise bending in long beams, unbraced against lateral deflection. 3. Danger of failure by the buckling of the web of steel beams of short span carrying heavy loads. See p. 17–47. 4. Danger of failure by horizontal shear, particularly in wooden beams.

**VERTICAL DEFLECTION.**—If a beam is to support or come in contact with materials like plaster, which may be broken by excessive deflection, it is usual to select such a beam that the maximum deflection will not exceed (1/360 × span). It may be shown that for a simple beam, supported at the ends, with a total uniformly distributed load $W$, pounds, the deflection, inches, is

$$y = 30\ sL^2/Ed \quad \ldots\ldots\ldots\ldots [10]$$

where $s$ = allowable unit fiber stress, lb. per sq. in.; $L$ = span of beam, ft.; $E$ = modulus of elasticity, lb. per sq. in.; $d$ = depth of beam, in.

If the deflection of a steel beam is to be less than $^1/_{360}$ of the span, it may be shown from equation [10] that, for a maximum allowable fiber stress of 18,000 lb. per sq. in., the limit of span, in feet, is approximately 1.8 $d$, where $d$ = depth of the beam, in.

For the deflection due to the impact of a moving load falling on a beam, see p. 7-15.

**LATERAL DEFLECTION, STEEL BEAMS.**—See p. 17–48.

**BUCKLING OF THE WEB, STEEL BEAMS.**—See p. 17–47.

**HORIZONTAL SHEAR IN TIMBER BEAMS.**—See Horizontal Shear, p. 7–19. In beams of a homogeneous material which can withstand equally well shearing stresses in any direction, vertical and horizontal shearing stresses are equally important. In timber, however, shearing strength along the grain is much less than that perpendicular to the grain. Hence, the beams may fail owing to horizontal shear. Short wooden beams should be checked for horizontal shear in order that allowable unit shearing stress along the grain shall not be exceeded. See Example 1, below.

**RESTRAINED BEAMS.**—A beam is considered to be restrained if one or both ends are not free to rotate. This condition exists if a beam is built into a masonry wall at one or both ends, if it is riveted or otherwise fastened to a column, or if the ends projecting beyond the supports carry loads which tend to prevent tilting of the ends which would naturally occur as the beam deflects. The shears and moments given in Table 2 for fixed end conditions are seldom, if ever, attained, since the restraining elements themselves deform and reduce the magnitude of the restraint. This reduction of restraint decreases the negative moment at the support and increases the positive moment in the central portion of the span. The amount of restraint which exists is a matter which must be judged for each case in the light of the construction used, the rigidity of the connections, and the relative sizes of the connecting members.

**SAFE LOADS ON SIMPLE BEAMS.**—Formula [11] gives the safe loads on simple beams. This formula is obtained by substituting in the flexure formula [5], the value of $M$ for a simple beam, uniformly loaded, as given in Table 2. Let $W$ = total load, lb.; $s$ = extreme fiber unit stress, lb. per sq. in.; $S$ = section modulus, in.$^3$; $L$ = length of span, ft. Then

$$W = {}^2/_3\, s(S/L) \quad \ldots\ldots\ldots\ldots [11]$$

If $s$ is taken as a maximum allowable unit fiber stress, this equation gives the maximum allowable load on the beam. Most building codes permit a value of $s$ = 18,000 lb. per sq. in. for quiescent loads on steel. For this value of $s$, equation [11] becomes

$$W = 12{,}000\ S/L \quad \ldots\ldots\ldots\ldots [12]$$

See p. 17–50 for tables of safe loads on structural steel beams, based on equation [12].

If the load is concentrated at the center of the span, the safe load is one-half the value given by equation [12]. If the load is neither uniformly distributed nor concentrated at the center of the span, the maximum bending moment must be used. The foregoing equations are for beams laterally supported and are for flexure only. The other factors which influence the strength of the beam, as shearing, buckling, etc., also must be considered. See pp. 17–47 to 17–49.

**USE OF TABLES IN DESIGN.**—For the use of tables of safe loads, and of properties of rolled structural steel sections, see pages 17–50 to 17–72. Examples of the use of these tables in the design of steel beams are there given. The following is an example in the use of tables for the design of a wooden beam.

EXAMPLE 1.—Design a southern pine girder, of common structural grade, to carry a load of 9600 lb. uniformly distributed over a 16-ft. span in the interior of a building, the beam being a simple beam, freely supported at each end.

*Solution.*—From Table 2, the bending moment of a simple beam uniformly loaded is $M = wl^2/8$. Since $W = wl$ and $L = 12\ l$,

$$W = 9600 \times 16 \times 12/8 = 230{,}400 \text{ lb.-in.}$$

From Table 3, the allowable unit stress on yellow pine is 1200 lb. per sq. in., whence

$$I/c = 230{,}400/1200 = 192 \text{ in.}^3$$

From Table 1, the section modulus of a rectangular section is $bd^2/6$. Assume $b = 8$ in. Then $8\,d^2/6 = 192$, and $d = \sqrt{144} = 12.0$ in. A beam 8 × 12 in. is selected tentatively, and checked for shear.

Maximum shearing stress (horizontal and vertical) is at the neutral surface over the supports. Formula [3] for horizontal shear in a solid rectangular beam is $s_s = 3\,V/2A$; $V = 9600/2 = 4800$, and $A = 8 \times 12 = 96$, whence $s_s = (3 \times 4800)/(2 \times 96) = 75$ lb. per sq. in.

From Table 4, the safe horizontal unit shearing stress for common grade southern yellow pine is 88 lb. per sq. in. Since the actual horizontal unit shearing stress is less than 88 lb., the 8 × 12 in. beam will be satisfactory.

**STRENGTH OF CAST-IRON BEAMS.**—(C. H. Benjamin, *Machy.*, May, 1906.)—Numerous tests were made of beams of different sections including hollow rectangles and cylinders, I- and T-shapes, etc. All the sections were made approximately the same area, about 4.4 sq. in., and all were tested by transverse loading, with supports 18 in. apart. The results, when reduced by the ordinary formula for stress on the extreme fiber, showed an extraordinary variation, some of the values being as follows: Square bar, 23,300; Round bar, 25,000. Hollow round, 3.4 in. outside and 2.5 in. inside diam., 26,450, and 35,800. Hollow ellipse, 3 in. wide, 3.9 in. high, 0.9 in. thick, 36,000. I-beam, 4 in. high, web 0.44 in. thick, 17,700. The hollow cylindrical and elliptical sections are much stronger than the solid sections. This is due to the thinner metal, the greater surface of hard skin, and freedom from shrinkage strains. Professor Benjamin's conclusions from these tests are:

1. The commonly accepted formulas for the strength and stiffness of beams do not apply well to cored and ribbed sections of cast-iron.
2. Neither the strength nor the stiffness of a section increases in proportion to the increase in the section modulus or the moment of inertia.
3. The best way to determine these qualities for a cast-iron beam is by experiment with the particular section desired and not by reasoning from any other section.

## 3. BEAMS OF UNIFORM STRENGTH

**A BEAM OF UNIFORM STRENGTH** is one in which the dimensions are such that the maximum fiber stress $s$ is the same throughout the length of the beam. The form of the beam is determined by finding the areas of various cross-sections from the flexure formula $M = sI/c$, keeping $s$ constant and making $I/c$ vary with $M$. For a rectangular section of width $b$ and depth $d$, the section modulus $I/c = {}^1/_6\,bd^2$ and, therefore, $M = {}^1/_6\,sbd^2$. By making $bd^2$ vary with $M$, the dimensions of the various sections are obtained. Table 5 gives the dimensions $b$ and $d$, at any section, the maximum unit fiber stress $s$, and the maximum deflection $y$, of some rectangular beams of uniform strength. In this table, the bending moment has been assumed to be the controlling factor. On account of the vertical shear near the ends of the beams, the area of the sections must be increased over that given by an amount necessary to keep the unit shearing stress within the allowable unit shearing stress. The discussion of beams of uniform strength, though of considerable theoretical interest, is of little practical value since the cost of fabrication will offset any economy in the use of the material. A plate girder in a bridge or a building is an approximation in practice to a steel beam of uniform strength.

## 4. CURVED BEAMS

The derivation of the flexure formula, $s = Mc/I$, assumes that the beam is initially straight; therefore, any deviation from this condition introduces an error in the value of the stress. If the curvature is slight the error involved is not large, but in beams with a large amount of curvature, as hooks, chain links, frames of punch presses, etc., the error involved in the use of the ordinary flexure formula is considerable. The effect of the curvature is to increase the stress in the inside and to decrease it on the outside fibers of the beam and to shift the position of the neutral axis from the centroidal axis toward the concave or inner side.

The correct value for the unit fiber stress may be found by introducing a correction factor in the flexure formula, *viz.*, $s = KMc/I$; the factor $K$ depends on the shape of the beam and on the ratio $R/c$, where $R$ = distance, inches, from the centroidal axis of the section to the center of curvature of the central axis of the unstressed beam; and $c$ = distance, inches, of centroidal axis from the extreme fiber on the inner or concave side. Seely's Advanced Mechanics of Materials contains an analysis of curved beams and also Table 6 which gives values of $K$ for a number of shapes and ratios of $R/c$. For slightly different shapes or proportions $K$ may be found by interpolation.

### Table 3.—Allowable Unit Stresses for Timber in Bending *

Recommended by the Forest Products Laboratory, Forest Service, U. S. Dept. of Agriculture.† All values are in pounds per square inch.

* Stress in tension. The working stresses recommended for fiber stress in bending may be safely used for tension parallel to grain.

† American lumber standards. Basic provisions for American lumber standards grades are published by the U. S. Dept. of Commerce, Simplified Practice Recommendation No. 16, Lumber, revised July 1, 1926; specifications for grades conforming to American lumber standards are published in the 1933 Standards A.S.T.M., and in *Amer. Ry. Eng. Assoc. Bull.*, vol. xxx, No. 314, Feb. 1929.

‡ Exact figures given. In order to preserve the exact numerical relations among working stresses for grades involving rate of growth and density requirements, the values for Douglas fir (western Wash. and Ore.) and for southern yellow pine have not been rounded off, as have the values for the other species.

### Table 4.—Allowable Unit Stresses for Timber in Compression and Shear

Recommended by the Forest Products Laboratory, U. S. Dept. of Agriculture.*
All values are in pounds per square inch.

---

* See footnote (†), Table 3.

† See footnote (‡), Table 3.

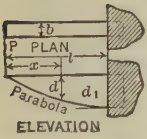
‡ The values for modulus of elasticity are average for species, and not safe working stresses. They may be used as given for computing average deflection of beams. To prevent sag in beams, values one-half those given should be used. For safe loads for long columns, values one-third those given should be used.

§ Values given are for the Select grade. Working stresses in compression, perpendicular to the grain, for common grades of Douglas fir (western Wash. and Ore.) and southern yellow pine are 325, 225, and 200, respectively, for continuously dry, occasionally wet but quickly dried, and more or less continuously damp or wet conditions.

‖ Joint details. The shearing stresses for joint details may be taken for any grade as 50% greater than the horizontal shear values for the Select grade.

**Table 5.—Rectangular Beams of Uniform Strength** *

$s$ = maximum fiber unit stress, pounds per square inch; $E$ = modulus of elasticity; $w$ = uniform load, pounds per inch; $d$ = depth of beam, inches; $b$ = width of beam, inches; $y$ = maximum deflection, inches. All other dimensions in inches.



**I. Cantilever Beam Loaded at Free End**

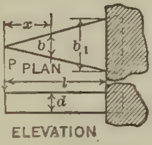
Width is constant. Depth varies.

$d = d_1\sqrt{x/l}$

$s = 6\,Pl/bd_1^2$

$y = 8\,Pl^3/Ebd_1^3$

Elevation is formed by a straight line and a parabola with its vertex at the loaded end.



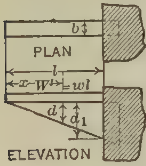
**II. Cantilever Beam Loaded at Free End**

Depth constant. Width varies.

$b = b_1x/l$

$s = 6Pl/b_1d^2$

$y = 6Pl^3/Eb_1d^3$



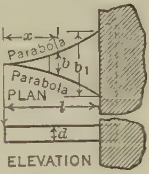
**III. Cantilever Beam Uniformly Loaded**

Width is constant. Depth varies.

$d = (x/l)d_1$

$s = 3\,wl^2/bd_1^2$

$y = 6wl^4/bEd_1^3$



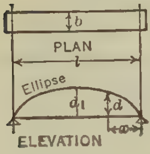
**IV. Cantilever Beam Uniformly Loaded**

Depth is constant. Width varies.

$b = b_1x^2/l^2$

$s = 3wl^2/b_1d^2$

$y = 3wl^4/b_1Ed^3$



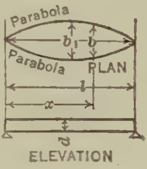
**V. Simple Beam Uniformly Loaded**

Width is constant. Depth varies.

$$d = \sqrt{\frac{4d_1^2(lx - x^2)}{l^2}}$$

$$s = \frac{3wl^2}{4bd_1^2}$$

Elevation is formed by a straight line and an ellipse.



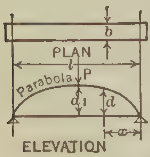
**VI. Simple Beam Uniformly Loaded**

Depth is constant. Width varies.

$$b = \frac{4b_1}{l^2}(lx - x^2)$$

$$s = \frac{3}{4}\frac{wl^2}{b_1d^2}$$

Plan is two parabolas, with vertices at center of span.



**VII. Simple Beam Loaded at Center of Span**

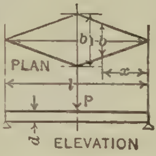
Width is constant. Depth varies.

$d = d_1\sqrt{2x/l}$

$$s = \frac{3}{2}\frac{Pl}{bd_1^2}$$

$$y = \frac{1}{2}\frac{Pl^3}{Ebd_1^3}$$

Elevation is a parabola with vertices at points of support.



**VIII. Simple Beam Loaded at Center of Span**

Depth is constant. Width varies.

$b = 2b_1x/l$

$$s = \frac{3}{2}\frac{Pl}{b_1d^2}$$

$$y = \frac{3}{8}\frac{Pl^3}{Eb_1d^3}$$

Plan is two triangles with vertices at points of support.

---

* The sections of the beams near the ends must be increased over the amounts shown to resist the vertical shear expressed by the formula $s = {}^3/_2V/A$.

## 5. CONTINUOUS BEAMS

As in simple beams, the expressions $M = sI/c$ and $s_s = V/A$ govern the design and investigation of beams resting on more than two supports. In the case of continuous beams, however, the reactions cannot be obtained in the manner described for simple beams. Instead, the bending moments at the various sections must be determined, and from these values the vertical shears at the sections and the reactions at the supports may be derived.

Consider the second span of length $l_2$, in., of the continuous beam, Fig. 7. Vertical shear $V_x$ at any section distant $x$, in. from the left support of the span is equal to the algebraic sum of all the vertical forces on one side of the section. Thus, if $V_2$ = vertical

* $Y_0$ is distance from centroidal axis to neutral axis, where beam is subjected to pure bending.

shear at a section to the right of, but infinitely close to, the left support, $w_2x$ = uniform load and $\Sigma P_2$ = sum of the concentrated loads along the distance $x$, applied at a distance $kl_2$ from the left support, $k$ being a fraction less than unity, then

$$V_x = V_2 - w_2 x - \Sigma P_2 \quad . \; . \; . \; . \; . \; . \; . \; . \; . \qquad [13]$$

At any section, distant $x$ from the left support, the bending moment is equal to the algebraic sum of the moments of all forces on one side of the section. If $M_2$ is the moment, lb.-in., at the support to the left,

$$M_x = M_2 + V_2 x - (w_2 x^2/2) - \Sigma P_2(x - kl_2) \quad . \; . \; . \qquad [14]$$

Assume that $x = l_2$. Then $M_x$ becomes the moment $M_3$ at the next support to the right, and the expression may be written

$$V_2 l_2 = M_3 - M_2 + (w_2 l_2^2/2) + \Sigma P_2(l_2 - kl_2) \; . \; . \; . \; . \qquad [15]$$

From formulas [13], [14], and [15] it is evident that the bending moment $M_x$ and the shear $V_x$ at any section between two consecutive supports may be determined if the bending moments $M_2$ and $M_3$ at those supports are known.

To determine bending moments at the supports an expression known as the *theorem of three moments is used.* This gives the relation between the moments at any three consecutive supports of a beam. For beams with the supports on the same level, and uniformly loaded over each span, the formula is

$$M_1 l_1 + 2\,M_2(l_1 + l_2) + M_3 l_2 = -\,{}^1\!/_4\, w_1 l_1^3 - {}^1\!/_4\, w_2 l_2^3 \quad . \; . \; . \qquad [16]$$

where $M_1$, $M_2$ and $M_3$ = moments of three consecutive supports; $l_1$ = length between first and second support; $l_2$ = length between second and third support; $w_1$ = uniform load per lineal unit over the first span; $w_2$ = uniform load per lineal unit over the second span. When both spans are of equal length and when the load on each span is the same, $l_1 = l_2$, $w_1 = w_2$, and formula [16] reduces to

$$M_1 + 4M_2 + M_3 = -\,{}^1\!/_2\, w\, l^2 \quad . \; . \; . \; . \; . \; . \; . \; . \; . \qquad [17]$$

which applies to most cases in practice.

Formulas [16] and [17] are used as follows: For any continuous beam of $n$ spans there are $(n + 1)$ supports. Assuming the ends of the beam to be simply supported without any overhang, the moments at the end supports are zero, and there are, therefore, to be determined $(n - 1)$ moments at the other supports. This may be done by writing $(n - 1)$ equations of the form of [16] and [17] for each support. These equations will contain $(n - 1)$ unknown moments and their solution will give values of $M_1$, $M_2$, $M_3$, etc., expressed as coefficients of $wl^2$. The shear $V_1$ at any support may be determined by substituting values of $M_1$ and $M_2$ in formula [15], and the bending moment at any point in any span may be obtained by formula [14]. The shear at any point in any span may be determined from formula [13].

Fig. 8 gives values and diagrams for the reactions, shears, and moments at all sections of continuous beams uniformly loaded up to five spans. Note that the reaction at any support is equal to the sum of the shears to the right and to the left of that support.

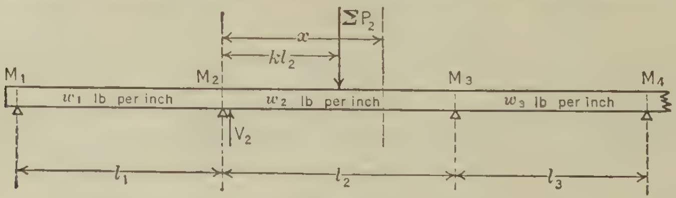

FIG. 7

## 6. AXIALLY END-LOADED BEAMS *

**DEFLECTION OF BEAM NEGLIGIBLE.**—When a beam is subjected to an axial end load as well as to a transverse bending load, the resultant unit stress developed at any point in the beam is the algebraic sum of the unit stresses produced by each of the loads acting independently of each other. If the beam of cross-sectional area $A$, sq. in., is considered so short that its deflection under load may be neglected, the unit stress produced at any cross-section of the beam by an axial load $P$, pounds, is $P/A$. The maximum unit stress (tensile or compressive), lb. per sq. in., due to the transverse or bending load is given by $s = M/(I/c)$ where $M$, lb.-in., is the maximum bending moment due to this load; $I$, in.$^4$, is the moment of inertia of the cross-section with respect to the neutral axis; $c$, in., is the distance from the neutral axis to the extreme fiber. If the axial load is compressive, the maximum unit stress is compressive, occurring at the top of the beam, and is

---

* Condensed from Seely, Resistance of Materials, 2nd Ed., Chapter VII.

$$s = (P/A) + (Mc/I) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [18]$$

The unit stress on the bottom fiber may be either tensile or compressive, according as $Mc/I$ is larger or smaller than $P/A$. If the longitudinal load $P$ were a tensile load, the maximum unit stress would occur on the bottom fiber and would be a tensile stress.

**DEFLECTION OF BEAM NOT NEGLIGIBLE.**—If the deflection of the beam is not negligible, the load $P$ cannot be considered an axial load with respect to any cross-sections except the end sections. The longitudinal load then has a moment arm equal to the deflection, and the stress due to this moment should be added algebraically to that caused by the other moments or loads. The stress due to deflection, $y$, inches (all other symbols as above), is $Pyc/I$. Thus, for a compressive longitudinal load, the maximum unit stress, lb. per sq. in., is at the top of the beam and is

$$s = (P/A) + (M + Py)(c/I) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [19]$$

Unit tensile stress, lb. per sq. in., at the bottom of the beam for the same load is

$$s = (-P/A) + (M + Py)(c/I) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [20]$$

Since the value of $y$ depends on the total bending moment $(M + Py)$, and the bending moment depends, in turn, on the value of $y$, equations [19] and [20] usually are solved by a method of approximation. The value of $y$ that would be caused by the cross-bending moment $M$, considered acting alone, is found first, and then is used in the expression, $M + Py$. This new value of the total bending moment is used to find a closer approximation to $y$. This operation may be repeated as many times as desired. When the deflection is small, as in comparatively short beams, the value of $y$ as found from the cross-bending moment above often is used without any further approximation.

Example.—Find the stress at the bottom and at the top of a timber beam 6 in. wide, 8 in. deep, and 12 ft. long, supported at each end, and carrying a distributed load of 400 lb. per ft., and also

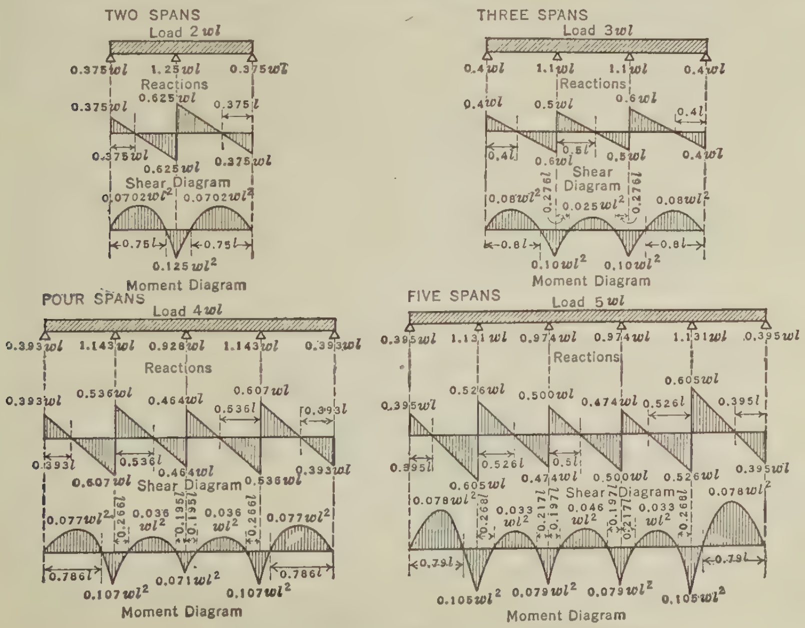

**Fig. 8. Shear and Moment Diagrams of Continuous Beams**

an axial compressive load of 10,000 lb. The modulus of elasticity of the timber may be taken as 1,600,000.

*Solution.*—Maximum unit stress will be at the center of the beam.

$$(P/A) = (10{,}000/48) = 208 \text{ lb. per sq. in.}$$

$$(Mc/I) = \{(400 \times 12 \times 144)/8\} \times \{6/(6 \times 8^2)\} = 1350 \text{ lb. per sq. in.}$$

See Table 2, p. 7–20.

$$y = \frac{5 \times 4800 \times 144^3 \times 12}{384 \times 6 \times 8^3 \times 1{,}600{,}000} = 0.456 \text{ in.}$$

$$Pyc/I = (10{,}000 \times 0.456 \times 6)/(6 \times 8^2) = 71 \text{ lb. per sq. in.}$$

Total unit compressive stress (top) = 208 + 1350 + 71 = 1629 lb. per sq. in.
Total unit tensile stress (bottom) = − 208 + 1350 + 71 = 1213 lb. per sq. in.
Here the stress due to deflection is small, as it usually will be in short deep beams.

# COLUMNS

## 1. DEFINITIONS

**A COLUMN OR STRUT** is a bar or structural member under axial compression, which has an unbraced length greater than about 8 or 10 times the least dimension of its cross-section. On account of its length, it is impossible to hold a column in a straight line under a load; a slight sidewise bending always occurs, causing flexural stresses in addition to the compressive stresses induced directly by the load. The lateral deflection will be in a direction perpendicular to that axis of the cross-section about which the moment of inertia is the least. Thus in Fig. 1*A* the column will bend in a direction perpendicular to *aa*; in Fig. 1*B* it will bend perpendicular to *aa* or *bb* and in Fig. 1*C* it is apt to bend in any direction.

**RADIUS OF GYRATION** of a section with respect to a given axis is equal to the square root of the quotient of the moment of inertia with respect to that axis, divided by the area of the section, that is

$$k = \sqrt{I/A}; \quad I/A = k^2 \quad . \; . \; . \; . \; . \; . \; . \; . \; . \quad [1]$$

where $I$ is the moment of inertia and $A$ the sectional area. Unless otherwise mentioned, an axis through the center of gravity of the section is the axis considered. As in beams, the moment of inertia is an important factor in the ability of the column to resist bending, but for purposes of computation it is more convenient to use the radius of gyration.

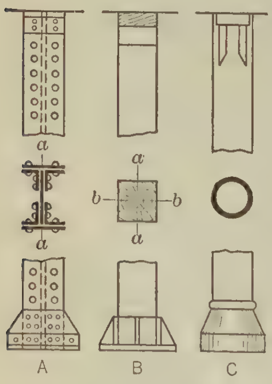

FIG. 1

**LENGTH OF A COLUMN** is the distance between points unsupported against lateral deflection.

**SLENDERNESS RATIO** is the length $l$ divided by the least radius of gyration $k$, both in inches. For steel, a *short column* is one in which $l/k < 20$ or 30, and its failure under load is due mainly to direct compression; in a *medium length column*, $l/k =$ about 30 to 175, and it will fail by a combination of direct compression and bending; in a *long column*, $l/k >$ about 175–200, and it will fail mainly by bending. For timber columns these ratios are about 0–30, 30–90, and above 90 respectively. The load which will cause a column to fail decreases as $l/k$ increases. The above ratios apply to round-end columns. If the ends are fixed (see below), the effective slenderness ratio is one-half of that for round-end columns, as the distance between the points of inflection is one-half the total length of the column. For flat ends it is intermediate between the two.

**CONDITION OF ENDS.**—The various conditions which may exist at the ends of columns usually are divided into four classes: 1. Columns with round ends; the bearing at either end has perfect freedom of motion, as there would be with a ball-and-socket joint at each end. 2. Columns with hinged ends; have perfect freedom of motion at the ends in one plane, as in compression members in bridge trusses where loads are transmitted through end pins. 3. Columns with flat ends; the bearing surface is normal to the axis of the column and of sufficient area to give at least partial fixity to the ends of the columns against lateral deflection. 4. Columns with fixed ends; the ends are rigidly secured, so that under any load the tangent to the elastic curve at the ends will be parallel to the axis in its original position.

Experiments prove that columns with fixed ends are stronger than columns with flat, hinged, or round ends, and that columns with round ends are weaker than any of the other types. Columns with hinged ends are equivalent to those with round ends in the plane in which they have free movement; columns with flat ends have a value intermediate between those with fixed ends and those with round ends. It often happens that columns have one end fixed and one end hinged, or some other combination. Their relative values may be taken as intermediate between those represented by the condition at either end. The extent to which strength is increased by fixing the ends depends on the length of column, fixed ends having a greater effect on long columns than on short ones.

## 2. COLUMN FORMULAS

There is no exact theoretical formula which gives the strength of a column of any length under an axial load. Formulas involving the use of empirical coefficients have been deduced, however, and they give results which are consistent with the results of tests of full-sized members.

**EULER'S FORMULA** assumes that the failure of a column is due solely to the stresses induced by sidewise bending. This assumption is not true for very short columns, which fail mainly by direct compression, nor is it true for columns of medium length. The failure in such cases is by a combination of direct compression and bending. For columns in which $l/k > 200$, Euler's formula is approximately correct and agrees closely with the results of tests.

Let $P$ = axial load, lb.; $l$ = length of column, in.; $I$ = least moment of inertia, in.$^4$; $k$ = least radius of gyration, in.; $E$ = modulus of elasticity; $y$ = lateral deflection, in., at any point along the column, that is caused by load $P$. If a column has round ends, so that the bending is not restrained, the equation of its elastic curve is

$$EI(d^2y/dx^2) = -Py, \qquad [2]$$

when the origin of the coordinate axes is at the top of the column, the positive direction of $x$ being taken downwards and the positive direction of $y$ in the direction of the deflection. Integrating the above expression twice and determining the constants of integration, there results

$$P = \Omega\pi^2 EI/l^2 \qquad [3]$$

which is Euler's formula for long columns. The factor $\Omega$ is a constant depending on the condition of the ends. For round ends $\Omega = 1$; for fixed ends $\Omega = 4$; for one end round and the other fixed $\Omega = 2.05$. $P$ is the load at which, if a slight deflection is produced, the column will not return to its original position; if $P$ is decreased the column will approach its original position but if $P$ is increased the deflection will increase until the column fails by bending.

For columns with value of $l/k$ less than about 150, Euler's formula gives results distinctly higher than those observed in tests. Euler's formula is now little used except for long members and as a basis for the analysis of the stresses in some types of structural and machine parts. It always gives an *ultimate* and never an allowable load.

**SECANT FORMULA.**—The deflection of the column is used in the derivation of the Euler formula, but if the load were truly axial it would be impossible to compute the deflection. If the column is assumed to have an initial eccentricity of load of $e$ in. (see Seely, Resistance of Materials, 2nd Ed., p. 212, for suggested values of $e$), the equation for the deflection $y$ becomes

$$y_{\max.} = e\{\sec (l/2)(\sqrt{P/EI}) - 1\} \qquad [4]$$

The maximum unit compressive stress becomes

$$s = (P/A)\{1 + (ec/k^2) \sec (l/2)\sqrt{P/EI}\} \qquad [5]$$

where $l$ = length of column, in.; $P$ = total load, lb.; $A$ = area, sq. in.; $I$ = moment of inertia, in.$^4$; $k$ = radius of gyration, in.; $c$ = distance from neutral axis to the most compressed fiber, in.; $E$ = modulus of elasticity; $I$ and $k$ both are taken with respect to the axis about which bending takes place. Because the formula contains the secant of the angle $(l/2)\sqrt{P/EI}$ it is sometimes called the *secant formula*. It has been suggested by the committee on Steel-Column Research (*Trans.*, A.S.C.E., 1933) that the best rational column formula can be constructed on the secant type, though of course it must contain experimental constants.

The secant formula can be used also for columns that are eccentrically loaded, if $e$ is taken as the actual eccentricity plus the assumed initial eccentricity.

**RANKINE'S FORMULA** is a modification of an earlier formula by Gordon, and sometimes is called Gordon's Formula. It applies to columns of slenderness ratios of 20

**Table 1.—Value of Coefficient $\phi$ in Rankine's Formula**

| Material | Both Ends Fixed | Fixed and Round | Both Ends Round |
|---|---|---|---|
| Timber | 1/3000 | 1.95/3000 | 4/3000 |
| Cast iron | 1/5000 | 1.95/5000 | 4/5000 |
| Wrought iron | 1/36,000 | 1.95/36,000 | 4/36,000 |
| Steel | 1/25,000 | 1.95/25,000 | 4/25,000 |

to 200, which are usually required in practice. Rankine's formula assumes that the maximum unit stress, $s$, lb. per sq. in., occurs in the fiber most remote from the axis on the concave side of the deflected column, and is equal to the sum of the direct unit compressive stress and the unit compressive stress due to bending alone; that is, $s = (P/A) + s_1$, where $P$ = load, lb.; $A$ = sectional area, sq. in.; $s_1$ = unit compressive stress due to bending, lb. per sq. in. The value of $s_1$ in this equation may be expressed in terms of $P$ by using the flexure formula, since the action is analogous to that of beams. Let $l$ = length of the column, in.; $I$ = least moment of inertia, in.$^4$; $k$ = corresponding radius of gyration, in.; $c$ = distance from axis to the remotest fiber on the concave side, in.; $y$ = lateral deflection of column, in. Substituting in the flexure formula, $s_1 = Mc/I$, and by replacing $M$ by its value $Py$ and $I$ by its value $Ak^2$, $s_1 = Pyc/(Ak^2)$. Hence maximum unit compressive stress on the remotest fiber on the concave side is equal to $P/A + Pyc/(Ak^2)$. By analogy with the theory of beams the deflection $y$ varies as $l^2/c$, so that by introducing an experimental coefficient $\phi$, the expression for maximum unit stress may be written

$$s = (P/A) + \phi(Pl^2/Ak^2) = (P/A)[1 + \phi(l/k)^2] \quad . \quad . \quad . \quad . \quad [6]$$

which is Rankine's formula for the investigation of columns. Variations in the value of $\phi$ have been determined by many experiments on columns of different materials and different conditions of ends. Values in Table 1, given by Merriman, have been used extensively in the past. Present practice (1937) tends toward the use of the same constant for all end conditions, as tests show that for columns of the proportions in common use, variations in material are more important than variations in end conditions.

The value to be taken for $s$ in Rankine's formula is the ultimate compressive stress of the material for rupture, and the allowable compressive unit stress for design. Rankine's formula may be used in the investigation of an existing column by comparing the computed value of $s$ with the proportional limit and with the ultimate strength of the material, thus determining the factor of safety. Similarly, the safe load $P$ for an existing column may be computed by assuming an allowable unit stress $s$.

**STRAIGHT-LINE FORMULA.**—Plotted results of actual tests on columns show that the relation between ultimate load and $l/k$ is fairly well represented by a straight line, for columns which fail by flexure of the whole column and not by local collapse. For a value of $l/k = 0$, average unit stress, $P/A$, on the section, is equal to the ultimate stress in compression for brittle materials and to the yield point in compression for ductile materials. From the point thus determined the straight line representing the average results of tests is drawn tangent to the curve of Euler's formula for the material. The equation of the straight line is

$$P/A = s - Cl/k \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [7]$$

where $s$ = ultimate unit stress in compression for a brittle material, or unit stress at the yield point in compression for a ductile material; $C$ = an experimental constant. Table 2 gives average values of $s$ and $C$ for structural steel, cast iron, and wood. The loads given by the straight-line formula using the constants in this table are *ultimate loads.* For design the straight-line formula usually is put in a form which gives allowable loads directly, constants $s$ and $C$ being divided by a factor of safety. The straight-line formula is not suitable for investigating a column, *i.e.*, determining values of $s$ due to given loads, as $(Cl/k)$ is not a function of $(P/A)$. It may be used to find the safe load for a given column under a given unit stress, or to design a column for a given load and unit stress.

**Table 2.—Ultimate Strength Constants for the Straight-line Column Formula**

| Material | $s_1$ lb. per sq. in. | Character of Ends | | | | | |
|---|---|---|---|---|---|---|---|
| | | Round | Fixed | 1 round 1 fixed | Round | Fixed | 1 round 1 fixed |
| | | $C$ | | | Limit of $(l/k)$ | | |
| Structural steel | 35,000 | 150 | 75 | 100 | 160 | 320 | 240 |
| Cast iron | 34,000* | 175 | 88 | 116 | 90 | 160 | 115 |
| Wood | 5,000* | 40 | 20 | 30 | 75 | 150 | 112 |

* This is less than the ultimate in compression for small specimens of cast iron or wood, but from tests of full-size columns it seems to be the value to be used for full-size castings or timbers which may contain defects.

## 3. WOODEN COLUMNS

**WOODEN COLUMN FORMULAS.**—One of the principal formulas is that formerly used by the A.R.E.A., $P/A = s_1(1 - l/60d)$, where $P/A$ = allowable unit load, lb. per sq. in.; $s_1$ = allowable unit stress in direct compression on short blocks, lb. per sq. in.; $l$ = length, in.; $d$ = least dimension, in. This formula is being replaced rapidly by formulas recommended by the A.S.T.M. and A.R.E.A. Committees of these societies, working with the U. S. Forest Products Laboratory, classified timber columns into three groups, as follows (A.S.T.M. Standards, 1933, D245–33):

**1. Short Columns.**—The ratio of unsupported length to least dimension does not exceed 10. For these columns, the allowable unit stress should not be greater than the values given in Table 4, under compression parallel to the grain.

**2. Intermediate-length Columns.**—Where the ratio of unsupported length to least dimension is greater than 10, formula [8], of the fourth power parabolic type, shall be used to determine allowable unit stress, until this allowable unit stress is equal to $^2/_3$ of the allowable unit stress for short columns.

$$(P/A) = s_1\{1 - {}^1/_3\,(l/Kd)^4\} \quad . \; . \; . \; . \; . \; . \; . \; . \quad [8]$$

where $P$ = total load, lb.; $A$ = area, sq. in.; $s_1$ = allowable unit compressive stress parallel to grain, lb. per sq. in.; see Table 4. $l$ = unsupported length, in.; $d$ = least dimension, in.; $K = l/d$ at the point of tangency of the parabolic and Euler curves, at which $P/A = (2/3)\,s_1$. The value of $K$ for any species and grade is $(\pi/2\sqrt{E/6\,s_1})$, where $E$ = modulus of elasticity.

**3. Long Columns.**—Where $P/A$ as computed by formula [8] is less than $^2/_3\,s_1$, formula [9] of the Euler type, which includes a factor of safety of 3, shall be used:

$$P/A = {}^1/_{36}\{\pi^2\,E/(l/d)^2\} \quad . \; . \; . \; . \; . \; . \; . \; . \; . \quad [9]$$

Timber columns should be limited to a ratio of $l/d$ equal to 50. No higher loads are allowed for square-ended columns. The strength of round columns may be considered the same as that of square columns of the same cross-sectional area.

**USE OF TIMBER COLUMN FORMULAS.**—The values of $E$ (modulus of elasticity) and $s_1$ (compression parallel to grain) to be used in the above formulas are given in Table 4. Table 3 gives the computed values of $K$ for some common types of timbers. These may be substituted directly in formula [8] for intermediate-length columns, or may be used in conjunction with Table 4, which gives the strength of columns of intermediate length, expressed as a percentage of strength ($s_1$) of short columns. In the tables, the term "continuously dry" refers to interior construction where there is no excessive dampness or humidity; "occasionally wet but quickly dry" refers to bridges, trestles, bleachers and grandstands; "usually wet" refers to timber in contact with the earth or exposed to waves or tide-water.

**Table 3.—Values of $K$ for Columns of Intermediate Length**

A.S.T.M. Standards, 1933, D245–33

| Species | Continuously dry | | Occasionally wet | | Usually wet | |

## 4. STEEL COLUMNS

**TYPES.**—Two general types of steel columns are in use: 1. Rolled shapes; 2. Built-up sections. The rolled shapes are easily fabricated, accessible for painting, neat in appearance where they are not covered, and convenient in making connections. A disadvantage is the probability that thick sections are of lower-strength material than thin sections because of the difficulty of adequately rolling the thick material. For the effect of thickness of material on yield point, see *Trans.* A.S.C.E., vol. xcviii, p. 1377, 1933.

**Table 4.—Strength of Columns of Intermediate Length, Expressed as a Percentage of Strength of Short Columns**

A.S.T.M. Standards, 1933, D245–33

Values for expression $\{1 - \frac{1}{3}(l/Kd)^4\}$ in formula [8]

| $K$ | Ratio of Length to Least Dimension in Rectangular Timbers, $l/d$ | | | | | | | | | | | | | | | | | | | |

NOTE: This table can also be used for columns not rectangular, the $l/d$ being equivalent to $0.289\ l/k$, where $k$ is the least radius of gyration of the section.

**GENERAL PRINCIPLES IN DESIGN.**—The design of steel columns is always a cut-and-try method, as no law governs the relation between area and radius of gyration of the section. A column of given area is selected, and the amount of load that it will carry is computed by the proper formula. If the allowable load so computed is less than that to be carried, a larger column is selected and the load for it computed, the process being repeated until a proper section is found.

A few general principles should guide in proportioning columns. The radius of gyration should be approximately the same in the two directions at right angles to each other; the slenderness ratio of the separate parts of the column should not be greater than that of the column as a whole; the different parts should be adequately connected in order that the column may function as a single unit; the material should be distributed as far as possible from the center line in order to increase the radius of gyration. See pp. 17–74 to 17–78 for tables of safe loads on rolled steel columns and data on their selection.

**STEEL COLUMN FORMULAS.**—A variety of steel column formulas are in use, differing mostly in the value of unit stress allowed with various values of $l/k$. See Eshbach, Handbook of Engineering Fundamentals, p. 5–42, forming Vol. 1, of this series, for a discussion of the several formulas.

**TESTS ON STEEL COLUMNS.**—Following the collapse of the Quebec Bridge in 1907 as a result of a column failure, the A.S.C.E., the A.R.E.A., and the U. S. Bureau of Standards co-operated in tests of full-size steel columns. The results of these tests are reported in *Trans.* A.S.C.E., vol. lxxxiii. pp. 1583–1688, 1919–20, and are summarized in Eshbach, Handbook of Engineering Fundamentals, pp. 5–43, 5–44. The tests showed that, for columns of the proportions commonly used, the effect of variation in the steel, kinks, initial stresses, and similar defects in the column was more important than the effect of length. They also showed that the thin metal gave definitely higher strength, per unit area, than the thicker metal of the same type of section.

## 5. ECCENTRIC AND TRANSVERSE LOADS ON COMPRESSION MEMBERS

**ECCENTRIC LOADS ON SHORT COMPRESSION MEMBERS.**—Where a direct push acting on a member does not pass through the centroid but at a distance $e$, inches, from it, both direct and bending stresses are produced. For short compression members in which column action may be neglected, the direct unit stress is $P/A$, where $P$ = total load, lb., and $A$ = area of cross-section, sq. in. The bending unit stress is $Mc/I$, where $M = Pe$ = bending moment, lb.-in.; $c$ = distance, in., from the centroid to the fiber in which the stress is desired; $I$ = moment of inertia, in.$^4$. The total unit stress at any point in the section is $s = P/A + Pec/I$, or $s = (P/A)(1 + ec/k^2)$, since $I = Ak^2$, where $k$ = radius of gyration, in.

**ECCENTRIC LOADS ON COLUMNS.**—Various column formulas must be modified when the loads are not balanced, that is, when the resultant of the loads is not in line with the axis of the column. If $P$ = load, lb., applied at a distance $e$ in. from the axis, bending moment $M = Pe$. Maximum unit stress $s$, lb. per sq. in., due to this bending moment alone, is $s = Mc/I = Pec/Ak^2$, where $c$ = distance, in., from the axis to the most remote fiber on the concave side; $A$ = sectional area, sq. in.; $k$ = radius of gyration in the direction of the bending, in. This unit stress must be added to the unit stress that would be induced if the resultant load were applied in line with the axis of the column. The modified formulas, expressed in allowable load per unit of area, are:

Modified Rankine's formula for eccentric loads (see p. 7–35):

$$P/A = s/\{1 + \phi(l/k)^2 + (ec/k^2)\} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [10]$$

Modified straight-line formula for eccentric loads (see p. 7–36):

$$P/A = \{s - (Cl/k)\}/\{1 + (ec/k^2)\} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [11]$$

The secant formula, p. 7–35, also can be used for columns that are eccentrically loaded if $e$ is taken as the actual eccentricity plus the assumed initial eccentricity.

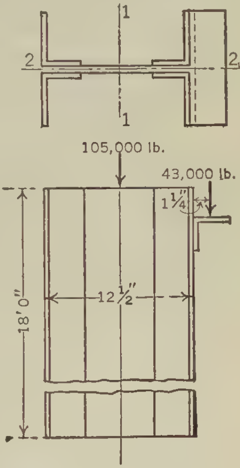

FIG. 2

EXAMPLE.—Design a steel column 18 ft. long to carry an axial load of 105,000 lb. and an additional load of 43,000 lb. which comes from a crane runway, and which is 1 1/4 in. beyond the outside edge of the column.

The formula used will be the A.I.S.C. formula,

$$P/A = 18{,}000/\{1 + (l^2/18{,}000k^2)\},$$

The shape selected will be a plate and four angles, Fig. 2.

Using 10,000 lb. per sq. in. as a preliminary estimate for the first selection, one plate 12 × 5/16 in. and four angles 5 × 3 1/2 × 3/8 in. will have an area of 15.95 sq. in. The safe load for this column will now be found. The moment of inertia $I_{1-1}$ is 412 in.$^4$, the radius of gyration $k_{1-1}$ is 5.08 in., and the radius of gyration $k_{2-2}$ is 2.08 in.

Considering the safe load with respect to axis 2–2 about which neither load is eccentric,

$$P = \frac{15.95 \times 18{,}000}{1 + \dfrac{(18 \times 12)^2}{18{,}000 \times (2.08)^2}} = 179{,}400 \text{ lb.}$$

Consider now the safe load about axis 1–1, with respect to which the load of 105,000 lb. is axial, and the load of 43,000 lb. has an eccentricity of 7 1/2 in. The load of 43,000 lb. will produce a stress due to its eccentricity, and this stress will reduce by that amount the unit load that the column can carry. The safe load will therefore be

$$P = 15.95\left(\frac{18{,}000}{1 + \dfrac{(18 \times 12)^2}{18{,}000 \times (5.08)^2}} - \frac{43{,}000 \times 7.5 \times 6.25}{412}\right) = 183{,}000 \text{ lb.}$$

The area exceeds that needed by about 3 sq. in.; the next smaller size is one plate 12 × 5/16 in. and four angles 5 × 3 1/2 × 5/16 in. The area is 13.99 sq. in., moment of inertia, $I_{1-1}$ = 356 in.$^4$, $k_{1-1}$ = 5.04 in., and $k_{2-2}$ = 2.03 in. With respect to the axis 2–2

$$P = \frac{13.99 \times 18{,}000}{1 + \dfrac{(18 \times 12)^2}{18{,}000 \times (2.03)^2}} = 154{,}600 \text{ lb.}$$

with respect to axis 1–1,

$$P = 13.99\left(\frac{18{,}000}{1 + \dfrac{(18 \times 12)^2}{18{,}000 \times (5.04)^2}} - \frac{43{,}000 \times 7.5 \times 6.25}{356}\right) = 149{,}300 \text{ lb.}$$

As the load to be carried is 148,000 lb. this column is satisfactory.

**COLUMN SUBJECTED TO TRANSVERSE OR CROSS-BENDING LOADS.**—(See Seely, Resistance of Materials, 1st Ed., p. 247.) A compression member that is subjected to cross-bending loads may be considered to be (1) a beam subjected to end thrust as discussed on p. 7–32 or (2) a column subjected to cross-bending loads, depending on the relative magnitude of the end thrust and cross-bending loads, and on the dimensions of the member. The various column formulas may be modified so as to include the effect of cross-bending loads. In this form they are:

Modified Rankine's Formula for transverse loads:

$$s = (P/A)\{1 + \phi(l^2/k^2) + (Pyc/Ak^2) + (Mc/Ak^2) \quad . \quad . \quad . \quad . \quad . \quad [12]$$

Modified straight-line formula for transverse loads:

$$P/A = \{s - (Cl/k)\} - (Pyc/Ak^2) - (Mc/Ak^2) \quad . \quad . \quad . \quad . \quad . \quad [13]$$

Modified secant formula for transverse loads:

$$s = (P/A)\{1 + (e + y)(c/k^2) \sec (l/2k)(\sqrt{P/AE}) + (Mc/Ak^2) \quad . \quad . \quad [14]$$

In these formulas, $s$ = maximum unit stress on concave side, lb. per sq. in.; $P$ = axial end load, lb.; $A$ = cross-sectional area, sq. in.; $M$ = moment due to cross-bending load, lb.-in.; $y$ = deflection due to cross-bending load, in.; $k$ = radius of gyration, in.; $l$ = length of column, in.; $e$ = assumed initial eccentricity, in.; $c$ = distance, in., from axis to the most remote fiber on the concave side; $C$ = experimental constant (see Table 2). The modified straight-line formula, like the straight-line formula, cannot be used to solve for $s$.

## 6. CAST-IRON COLUMNS

Hollow cast-iron columns are used to a limited extent in buildings of moderate height, because of cheapness, and because of the fact that they save space, as compared to wood columns. They have the disadvantage of uncertain strength, due to hidden defects, variation in wall thickness resulting from shifting of the core, and internal stresses from uneven cooling of the casting. Because of these variables, it is difficult to devise a satisfactory formula for design. Their use generally is governed by municipal building laws. The New York City building law, 1929, gives the formula $P/A = 9000 - 40(l/k)$, where $P$ = safe load, lb.; $A$ = area of section, sq. in.; $l$ = length, in.; $k$ = least radius of gyration. Most building laws specify a minimum metal thickness of $^1/_2$ to $^3/_4$ in.; minimum diameter, 6 in.; maximum length, 20 × diameter, or 70 × least radius of gyration. If it is necessary to use a wall thicker than 2 in., a steel column will be more economical.

Tables of safe loads allowed by the New York City Building Code on round and square hollow cast-iron columns will be found in Eshbach, Handbook of Engineering Fundamentals, pp. 5–46, 5–47, forming Vol. 1 of this series.

# SHAFTS

## 1. DEFINITIONS

**TORSIONAL STRESS.**—A bar is under torsional stress when it is held fast at one end and a force acts at the other end to twist the bar. In a round bar, Fig. 1, with a constant force acting, the straight line $ab$ becomes the helix $ad$, and a radial line in the cross-section, $ob$, moves to the position $od$. The angle $bad$ remains constant while the angle $bod$ increases with the length of the bar. Each cross-section of the bar tends to shear off the one adjacent to it, and in any cross-section the shearing stress at any point is normal to a radial line drawn through the point. Within the shearing proportional limit, a radial line of the cross-section remains straight after the twisting force has been applied, and the unit shearing stress at any point is proportional to its distance from the axis.

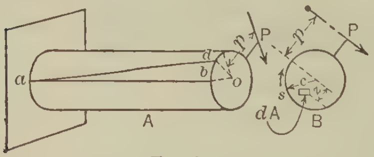

Fig. 1

**TWISTING MOMENT,** $T$, is equal to the product of the resultant, $P$, of the twisting forces, multiplied by its distance from the axis, $p$.

**RESISTING MOMENT,** $T_r$, in torsion, is equal to the sum of the moments of the unit shearing stresses acting along a cross-section with respect to the axis of the bar. If $dA$ is an elementary area of the section at a distance of $z$ units from the axis of a circular shaft (Fig. 1B), and $c$ is the distance from the axis to the outside of the cross-section where the unit shearing stress is $s$, then the unit shearing stress acting on $dA$ is $(sz/c)dA$, its moment with respect to the axis is $(sz^2/c)dA$, and the sum of all the moments of the unit shearing stresses on the cross-section is $\int(sz^2/c)dA$. In this expression the factor $\int z^2dA$ is the polar moment of inertia of the section with respect to the axis. Denoting this by $J$, the resisting moment may be written $sJ/c$.

**THE POLAR MOMENT OF INERTIA** of a surface about an axis through its center of gravity and perpendicular to the surface is the sum of the products obtained by multiplying each elementary area by the square of its distance from the center of gravity of its surface; it is equal to the sum of the moments of inertia taken with respect to two axes in the plane of the surface at right angles to each other passing through the center of gravity. It is represented by $J$, inches$^4$. For the cross-section of a round shaft,

$$J = (1/32)(\pi d^4), \quad \text{or} \quad 1/2\,\pi r^4 \qquad [1]$$

for a hollow shaft

$$J = (1/32)[\pi(d^4 - d_1^4)] \qquad [2]$$

where $d$ is the outside and $d_1$ the inside diameter, in inches, or

$$J = 1/2[\pi(r^4 - r_1^4)] \qquad [3]$$

where $r$ is the outside and $r_1$ the inside radius, in inches.

**THE POLAR RADIUS OF GYRATION,** $k_p$, sometimes is used in formulas; it is defined as the radius of a circumference along which the entire area of a surface might be concentrated and have the same polar moment of inertia as the distributed area. For a solid circular section,

$$k^2_p = (1/8)d^2 \qquad [4]$$

for a hollow circular section,

$$k^2_p = (1/8)(d^2 - d_1^2) \qquad [5]$$

## 2. DETERMINATION OF TORSIONAL STRESSES

**TORSION FORMULA FOR ROUND SHAFTS.**—The conditions of equilibrium require that the twisting moment, $T$, be opposed by an equal resisting moment, $T_r$, so that for the values of the maximum unit shearing stress, $s_s$, within the proportional limit, the torsion formula for round shafts becomes

$$T_r = T = s_s\,J/c \qquad [6]$$

If $s_s$ is in lb. per sq. in., then $T_r$ and $T$ must be in lb.-in., $J$ is in in.$^4$, and $c$ is in in. For solid round shafts having a diameter, $d$, in.,

$$J = (1/32)\,\pi d^4, \quad \text{and} \quad c = 1/2\,d \qquad [7]$$

and

$$T = (1/16)\,\pi d^3\,s_s, \quad \text{or} \quad s_s = 16\,T/\pi d^3 \qquad [8]$$

For hollow round shafts

$$J = \pi(d^4 - d_1^4)/32, \quad c = (1/2)\,d \qquad [9]$$

and the formula becomes

$$T = s_s\,\pi(d^4 - d_1^4)/16\,d \quad \text{or} \quad s_s = 16\,Td/\pi(d^4 - d_1^4) \qquad [10]$$

The torsion formula applies only to solid circular shafts or hollow circular shafts, and then only when the load is applied in a plane perpendicular to the axis of the shaft and when the shearing proportional limit of the material is not exceeded.

**SHEARING STRESS IN TERMS OF HORSEPOWER.**—If the shaft is to be used for the transmission of power, the value of $T$, lb.-in., in the above formulas becomes $63{,}030\,H/n$, where $H$ = horsepower to be transmitted; $n$ = r.p.m. The maximum unit shearing stress, lb. per sq. in., then, is:

$$\text{For solid round shafts:} \quad s_s = 321{,}000\,H/nd^3 \qquad [11]$$

$$\text{For hollow round shafts:} \quad s_s = 321{,}000\,Hd/n(d^4 - d_1^4) \qquad [12]$$

If $s_s$ is taken as the allowable unit shearing stress, the diameter, $d$, inches, necessary to transmit a given horsepower at a given shaft speed can then be determined. These formulas give the stress due to torsion only, and allowance must be made for any other loads, as the weight of shaft and pulleys, and tension in belts.

**ANGLE OF TWIST.**—When the unit shearing stress $s_s$ does not exceed the proportional limit, the angle *bod* (Fig. 1) for a solid round shaft may be computed from the formula

$$\theta = Tl/E_s\,J \qquad [13]$$

where $\theta$ = angle, radians; $l$ = length of shaft, in.; $E_s$ = shearing modulus of elasticity of the material; $T$ = twisting moment, lb.-in. Values of $E_s$ for different materials are: steel, 12,000,000; wrought iron, 10,000,000; and cast iron, 6,000,000.

When the angle of twist on a section begins to increase in a greater ratio than the twisting moment, it may be assumed that the shearing stress on the outside of the section has reached the proportional limit. The shearing stress at this point may be determined by substituting the twisting moment at this instant in the torsion formula.

**TORSION OF NON-CIRCULAR CROSS-SECTIONS.**—The analysis of shearing stress distribution along non-circular cross-sections of bars under torsion is complex. By drawing two lines at right angles through the center of gravity of a section before twisting, and observing the angular distortion after twisting, it has been found from many experiments that in non-circular sections the shearing unit stresses are not proportional to their distances from the axis. Thus in a rectangular bar there is no shearing stress at the corners

### Table 1.—Approximate Formulas for Maximum Shearing Stress and Angle of Twist in Members Subjected to Torsion

(From Seely's Advanced Mechanics of Materials)

$s_s$ = shearing unit stress, lb. per sq. in.; $T$ = twisting moment, lb.-in.; $\theta$ = angle of twist, radians, in length, $l$, in.; $J$ = polar moment of inertia, in.$^4$; $E_S$ = shearing modulus of elasticity; $A$ = area of cross-section, sq. in.; $y$ = distance of most remote edge from center of bar, in. Tests of brittle metal are those made by Bach, *Elastizität u. Festigkeit*, 1924, except for those marked *, which are by Kommers, *Am. Mach.*, vol. xl, p. 941, 1914.

| Any compact section without re-entrant angles. | $s_s = \frac{4\pi^2JT}{A^4y}$ | | $\theta = \frac{kJTl}{A^4E_s}$<br>$k = 4\pi^2$ for ellipse.<br>$= 40$ to $42$ for rectangles. |

of the sections and the stress at the middle of the wide side is greater than at the middle of the narrow side. In an elliptical bar the shearing stress is greater along the flat side than at the round side.

It has been found by tests (Bach, *Elastizität u. Festigkeit*; and Young, *Bull.* 4, School of Engg. Research, Univ. of Toronto) as well as by mathematical analysis that the torsional resistance of a section, made up of a number of rectangular parts, is approximately equal to the sum of the resistances of the separate parts. It is on this basis that nearly all the formulas for non-circular sections have been developed. For example, the torsional resistance of an I–beam is approximately equal to the sum of the torsional resistances of the web and the outstanding flanges. In an I–beam in torsion the maximum shearing stress will occur at the middle of the side of the web, except where the flanges are thicker than the web, and then the maximum stress will be at the mid-point of the width of the flange. Re-entrant angles, as those in I-beams and channels, are always a source of weakness in members subjected to torsion. Table 1 gives approximate values of the maximum unit shearing stress $s_s$ and the angle of twist $\theta$ induced by twisting bars of various cross-sections, it being assumed that $s_s$ is not greater than the proportional limit and that the modulus of elasticity, $E_s$, remains a constant.

**ULTIMATE STRENGTH IN TORSION.**—In a torsion failure, the outer fibers of a section are the first to shear and the rupture extends toward the axis as the twisting is continued. The torsion formula for round shafts has no theoretical basis after the shearing stresses on the outer fibers exceed the proportional limit, as the stresses along the section then are no longer proportional to their distances from the axis. It is convenient, however, to compare the torsional strength of various materials by using the formula to compute values of $s_s$ at which rupture takes place. These computed values of the maximum stress sustained before rupture are somewhat higher for iron and steel than the ultimate strength of the materials in direct shear. Computed values of the ultimate strength in torsion are found by experiment to be as follows: Cast iron, 30,000 lb. per sq. in.; wrought iron, 55,000 lb. per sq. in.; medium steel, 65,000 lb. per sq. in.; timber, 2000 lb. per sq. in. These computed values of twisting strength may be used in the torsion formula to determine the probable twisting moment that will cause rupture of a given round bar or to determine the size of a bar that will be ruptured by a given twisting moment. In design, large factors of safety should be taken, especially when the stress is reversed as in reversing engines and when the torsional stress is combined with other stresses as in shafting.

**EFFECT OF KEYWAY IN SHAFT.**—The sharp re-entrant angles in keyways produce high local stresses at these points. Based on studies made by hydrodynamical and soap-film methods, the local stress in the corner has been determined as equal to the stress in a similar shaft without a keyway, multiplied by a constant, $K$, which depends on the radius of the corner. The constants are, approximately:

| Radius of corner, in........ | 0.1 | 0.2 | 0.3 | 0.4 | 0.5 | 0.6 | 0.7 |
|---|---|---|---|---|---|---|---|
| $K$...................... | 5.4 | 3.4 | 2.7 | 2.3 | 2.1 | 2.0 | 1.9 |

Under steady loading these high stresses probably are not very important, as a ductile material allows an adjustment to take place, but if the shaft is subjected to repeated loads a crack may start at the corner.

Experiments by Moore (*Bull.* 42, Engg. Exp. Sta., Univ. of Ill., 1909) on shafts from $1\,^1/_4$ to $2\,^1/_4$ in. diameter showed that keyways reduced the elastic strength and the stiffness but did not reduce the ultimate strength. If $E'$ = ratio of strength at the proportional limit of a shaft with a keyway to strength at the proportional limit of a shaft without a keyway, $N$ = ratio of the angle of twist of a shaft with a keyway to that of a shaft without a keyway, $w$ = width of keyway divided by diameter of shaft, and $h$ = depth of keyway divided by diameter of shaft, the ratios obtained were: $E' = 1.0 - 0.2\,w - 1.1\,h$; $N = 1.0 + 0.4\,w + 0.7\,h$, for ranges of $w$ from 0.25 to 0.50, and of $h$ from 0.125 to 0.1875.

# CYLINDERS, PLATES AND ROLLERS

## 1. CYLINDERS

**THIN CYLINDERS UNDER INTERNAL PRESSURE.**—A cylinder is regarded as thin when the thickness of the wall is small compared with the diameter. It is assumed that in such cases the tensile stress across a longitudinal section is uniformly distributed over the thickness of the wall. If $p$ = internal pressure, lb. per sq. in.; $l$ = length of cylinder, in.; $t$ = thickness of wall, in.; $d$ = diameter of cylinder, in.; and $s$ = tensile stress, lb. per sq. in.,

$$pdl = 2\,stl \quad \text{or} \quad s = pd/2t \qquad [1]$$

For resistance to rupture in a circumferential seam, due to pressure on the ends of the cylinder, *i.e.*, the tensile stress across a transverse section,

$$p\pi d^2/4 = s\,t\pi d \quad \text{or} \quad s = pd/4t \qquad [2]$$

Comparing formulas [1] and [2], it is seen that the resistance to rupture around the circumference is twice the resistance to longitudinal rupture; for this reason cylindrical boilers are commonly single riveted in the circumferential seams and double or triple riveted in the longitudinal seams.

In using the above formulas to design cylindrical shells or piping, thickness $t$ must be increased to compensate for rivet holes in the joints. Water pipes, particularly those of cast iron, require a high factor of safety to provide security against shocks caused by water ram or rough handling before they are laid. Steam pipes also require a high factor of safety to resist shocks due to condensation and expansion of steam.

Formula [2] applies also to the stresses in the walls of a thin hollow sphere, hemisphere, or dome. This analysis does not apply where holes are cut in the cylinder for rivets or for other purposes. Where holes are cut, the tensile stresses must be found by the method used in riveted joints. See p. 9–49.

**Thickness of a Domed Head of a Boiler.**—If $s$ = safe unit tensile stress, $d$ = diameter of shell, in., and $t$ = thickness of unit shell, $t = pd \div 2s$; but the thickness of a hemispherical head of the same diameter is $t = pd \div 4s$. Hence, if we make the *radius* of curvature of a domed head equal to the diameter of the boiler, we shall have $t = 2\,pd/4s = pd/2s$ or the thickness of such a domed head will be equal to the thickness of the shell.

**THIN CYLINDERS UNDER EXTERNAL PRESSURE.**—Prof. Reid T. Stewart (*Trans.* A.S.M.E., xxvii, 730) made two series of tests on Bessemer steel lap-welded tubes 3 to 10 in. diam. One series was made on tubes 8 5/8 in. outside diam. with the different commercial thicknesses of wall, and in lengths of 2 1/2, 5, 10, 15 and 20 ft. between transverse joints tending to hold the tube in a circular form. A second series was made on single lengths of 20 ft. Seven sizes, from 3 to 10 in. outside diam., in all the commercial thicknesses obtainable, were tested. The principal conclusions drawn from the research were:

1. The length of tube, between transverse joints tending to hold it in circular form, has no practical influence on the collapsing pressure of a commercial lap-welded tube if this length is not less than about 6 diameters of tube.

2. The formulas based on this research, for the collapsing pressures of lap-welded Bessemer steel tubes, for all lengths greater than 6 diameters, are:

$$P = 1000\{1 - \sqrt{1 - 1600(t^2/d^2)}\} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [3]$$

$$P = 86{,}670(t/d) - 1386, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [4]$$

where $P$ = collapsing pressure, lb. per sq. in.; $d$ = outside diameter of tube, in.; $t$ = thickness of wall, in.

Formula [3] is for values of $P$ less than 581 lb., or for values of $t/d$ less than 0.023, while formula [4] is for values greater than these. When applying these formulas to practice, a suitable factor of safety must be used.

3. The apparent fiber stress under which the different tubes failed varied from about 7000 lb. for the relatively thinnest to 35,000 lb. per sq. in. for the relatively thickest walls. Since the average yield point of the material was 37,000 and the tensile strength 58,000 lb. per sq. in., it would appear that the strength of a tube subjected to a fluid collapsing pressure is not dependent alone on either the elastic limit or ultimate strength of the material constituting it. The element of greatest weakness in a tube is its departure from roundness, even when this departure is relatively small.

Table 1 is a condensed statement of the principal results of the tests. Table 2 has been calculated from Stewart's formulas.

Tests by Prof. A. P. Carmen (*Bull.* No. 5, Engg. Experiment Station, Univ. of Ill., 1906), showed that with ratios of $t/d$ of less than 0.025, for cold-drawn seamless steel tubes,

$$P = 50{,}200{,}000(t/d)^3 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [5]$$

and for seamless brass tubes,

$$P = 25{,}150{,}000(t/d)^3 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [6]$$

notation being as before.

For an extended discussion see Strength of Thin Cylindrical Shells under External Pressure by Saunders and Windenburg, and The Collapsing Strength of Steel Tubes by Jasper and Sullivan (*Trans.* A.S.M.E., Applied Mechanics, September-December, 1931, pp. 207–245).

**COLLAPSING PRESSURE OF COPPER TUBES.**—An investigation conducted by M. G. Steele for Revere Copper & Brass, Inc., is reported in *Jour.*, Am. Soc. Nav. Engrs., Nov., 1939. This investigation showed that tubes properly designed to resist substantial internal pressures usually will withstand any external pressure to which they might be inadvertently subjected. The formulas developed for collapse of steel and brass tubes do not appear to be applicable to copper tubes. The investigation consisted of collapsing tubes of various diameters and gages in different alloys, with an accompanying correlation of the physical properties of the tube material. The results of the investigation have been translated into the curves Figs. 1 and 2, which may be used as design data for copper tubes subject to external collapsing pressure. The curves apply to three types of tubes, as follows:

Type K, generally used for underground services, plumbing purposes and severe water conditions; also for gas, steam and oil lines, and other industrial uses. It is supplied in hard or soft temper.

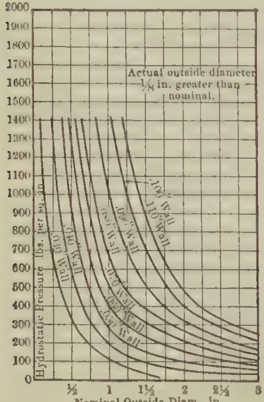

Fig. 1. Collapsing Pressure of Soft Copper Tubing.

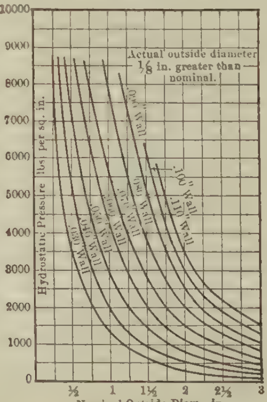

Fig. 2. Collapsing Pressure of Hard Copper Tubing.

Type L, used for general plumbing purposes and normal water conditions; also for gas, steam and oil lines and other industrial uses. Supplied in hard or soft temper.

Type M, used for general plumbing purposes with solder fittings only. Suitable for normal water conditions; also for gas, steam and oil lines and other industrial uses. Supplied usually in hard temper only.

In using the curves of Figs. 1 and 2, a suitable safety factor should be allowed to cover shock loads, water-hammer, etc. The usual factor of safety is 3 but this should be varied according to conditions and to engineering judgment. The values for hard tubes are considered more useful than those for soft tubes, hard tubes being used more often where collapse is a possibility. Soft tubes are not much used in mechanical applications except where bending is requisite. They usually are used to conduct water, gas or other fluids and the external pressures encountered are seldom great enough to cause collapse.

**THICK CYLINDERS.**—Timoshenko and Lessells (Applied Elasticity) and Swain (Strength of Materials) give the following formulas for the stresses in thick hollow cylinders under internal and external pressure. Under internal pressure only, the maximum tensile stress $s_t$ in a tangential direction on the inner surface is

$$s_t = p\{(a^2 + b^2)/(b^2 - a^2)\} \quad \ldots\ldots\ldots \quad [7]$$

where $p$ = internal pressure, lb. per sq. in.; $a$ = inside radius and $b$ = outside radius, in. Under internal pressure maximum compressive stress in a radial direction is on the inside and equals $p$ lb. per sq. in.

When the cylinder is subjected to an external pressure $p_e$ the maximum compressive unit stress will be at the inner surface and is

$$s_c = 2\,p_e\,b^2/(b^2 - a^2) \quad \ldots\ldots\ldots \quad [8]$$

In *shrinkage fits* a hollow cylinder or collar is forced over a cylinder having an outer diameter slightly greater than the inside diameter of the outer cylinder. This will cause compressive stresses in the inner cylinder and tensile stresses in the outer cylinder. Timoshenko and Lessells (Applied Elasticity) give the equation for the pressure $p$, lb. per sq. in. between the cylinders as

$$p = \frac{E\delta}{b}\,\frac{(b^2 - a^2)\,(c^2 - b^2)}{2b^2(c^2 - a^2)} \quad \ldots\ldots\ldots \quad [9]$$

where $E$ = modulus of elasticity, $a$ = inner radius of inner cylinder, $b$ = outer radius of inner cylinder, $c$ = outer radius of outer cylinder, $\delta$ = amount by which the outer radius of the inner cylinder exceeds the inner radius of the outer cylinder. With the pressures known, external pressure on the inner cylinder and internal pressure on the outer cylinder, the stresses can be computed by means of equations [7] and [8].

A comparison of the various theories of failure of thick cylinders is given in Seely's Advanced Mechanics of Materials from which the following is abstracted:

For brittle materials, the *maximum stress theory* is recommended. It gives:

For internal pressure only, $t = r_1[\{\sqrt{(s_w + p)/(s_w - p)}\} - 1]$ . . . . . . . [10]

For external pressure only, $t = r_1[\{\sqrt{s_w/(2p_e + s_w)}\} - 1]$ . . . . . . . . [11]

For ductile materials the *maximum strain theory* is recommended. It is used by the U. S. Government for the design of guns. For internal pressure only this theory gives

$$t = r_1\left[\left\{\sqrt{\frac{E\epsilon_w + (1 - m)p}{E\,\epsilon_w - (1 + m)p}}\right\} - 1\right] \quad \ldots\ldots \quad [12]$$

and for external pressure only

$$t = r_1\left[\left\{\sqrt{\frac{E\,\epsilon_w}{E\,\epsilon_w - 2p_e}}\right\} - 1\right] \quad \ldots\ldots\ldots \quad [13]$$

where $t$ = thickness, in.; $s_w$ = allowable working unit stress, lb. per sq. in.; $p$ = internal pressure, and $p_e$ = external pressure, lb. per sq. in.; $r_1$ = inner radius of cylinder, in.; $E$ = modulus of elasticity; $m$ = Poisson's ratio; $\epsilon_w$ = allowable working unit deformation of the material.

**CORRUGATED FURNACES.**—The Board of Trade, Lloyd's Register, British Corporation and the Bureau Veritas have adopted the following uniform formula (see Kempe's Engineer's Yearbook, 1932) for allowable pressures on Fox type corrugated furnaces:

$$WP = 480(t - 1)/D \quad \ldots\ldots\ldots \quad [14]$$

where $D$ = external diameter, in., measured at the bottom of the corrugations; $t$ = thickness of furnace plate in 32nds of an inch, measured at the bottom of the corrugations or camber; $WP$ = allowable working pressure, lb. per sq. in. Thickness of plate is limited to $^{13}/_{16}$ in.

**HOLLOW COPPER BALLS.**—Hollow copper balls are used as floats in boilers or tanks, to control feed and discharge valves, and regulate the water-level. *The Locomotive* (Oct., 1891) gives two empirical rules for determining the thickness of a copper ball, which is to work under an external pressure, as follows:

1. Thickness = (diameter, in. × pressure, lb., per sq. in.)/16,000.
2. Thickness = (diameter × $\sqrt{\text{pressure}}$)/1240.

These rules give the same result for a pressure of 166 lb. per sq. in. only.

## 2. PLATES

**CIRCULAR FLAT PLATES.**—Table 3 gives equations for deflection and stresses in circular plates based mainly on the theoretical analyses developed by Grashof. (See Morley's Strength of Materials; Seely's Advanced Mechanics of Materials; Timoshenko and Lessells' Applied Elasticity.) Experience shows that the strength of flat plates is greater than is indicated by these equations.

**ELLIPTICAL FLAT PLATES.**—An approximate formula for the maximum stress $s$ in elliptical plates, simply supported at the edge, having a major axis $2a$, a minor axis $2b$, a thickness $t$, and carrying a distributed load of $w$ lb. per sq. in., is

$$s = \{(3a - 2b)/a\} \times (wb^2/t^2) \quad . \; . \; . \; . \; . \; . \; . \; . \quad [15]$$

**SQUARE FLAT PLATES.**—Where the load is $w$ lb. per sq. in. and the plate is supported on the four edges, each $b$ in. long, the maximum moment and maximum stress will be along a diagonal. The moment $M$ per unit length of diagonal will be $wb^2/24$, and, where $t$ = thickness, in., the unit stress will be

$$s = wb^2/4t^2 \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad [16]$$

With edges fixed and load distributed the maximum stress at the center of each edge is, approximately, $s = 0.20\, wb^2/t^2$. Nichols found in experiments with steel plates

$$s = 0.141\, wb^2/t^2 \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad [17]$$

and Bach found

$$s = 0.19\, wb^2/t^2 \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad [18]$$

**RECTANGULAR FLAT PLATES.**—For a distributed load $w$ lb. per sq. in., with supports along the four sides, and assuming a uniform distribution of moment along a

**Table 3.—Maximum Stresses and Deflection for Circular Flat Plates**

$m$ = Poisson's ratio; $P$ = concentrated load, lb.; $w$ = distributed load, lb. per sq. in.; $r$ = radius of plate, in.; $t$ = thickness of plate, in.; $E$ = modulus of elasticity.

| Type of Load and Support | Maximum Stress at Edge | Maximum Stress at Center | Maximum Deflection at Center, $m = 1/3$ |
|---|---|---|---|
| Uniform load, edge simply supported | | $\frac{3}{8}\frac{wr^2}{t^2}(3 + m)$ | $\frac{2}{3}\frac{wr^4}{Et^3}$ |
| Uniform load, edge fixed | Radial direction<br>$\frac{3}{4}\frac{wr^2}{t^2}$<br>Tangential direction<br>$\frac{3}{4}\frac{wmr^2}{t^2}$ | $\frac{3}{8}\frac{wr^2}{t^2}(1 + m)$ | $\frac{1}{6}\frac{wr^4}{Et^3}$ |

| $a/b$ | $D$ | $K_1$ | $K_2$ | $a/b$ | $D$ | $K_1$ | $K_2$ |
|---|---|---|---|---|---|---|---|
| 1.0 | 0.0443 | 0.0479 | 0.0479 | 1.8 | 0.1017 | 0.0948 | 0.0479 |
| 1.1 | .0530 | .0553 | .0494 | 1.9 | .1064 | .0985 | .0471 |
| 1.2 | .0616 | .0626 | .0501 | 2.0 | .1106 | .1017 | .0464 |
| 1.3 | .0697 | .0693 | .0504 | 3.0 | .1336 | .1189 | .0404 |
| 1.4 | .0770 | .0753 | .0506 | 4.0 | .1400 | .1235 | .0384 |
| 1.5 | .0843 | .0812 | .0500 | 5.0 | .1416 | .1246 | .0375 |
| 1.6 | .0906 | .0862 | .0493 | ∞ | .1422 | .1250 | .0375 |
| 1.7 | .0964 | .0908 | .0486 | | | | |

diagonal, Seely gives (Advanced Mechanics of Materials, p. 141) the stress as

$$s = a^2 b^2 w / \{2t^2(a^2 + b^2)\} \qquad [19]$$

where $a$ is the length of the long side and $b$ the length of the short side.

For rectangular plates fixed along the four sides, Bach found experimentally for ductile materials that the coefficient $K$ in the moment equation $M = Kwb^2$ was such that the moment along the fixed edge and along the center was about the same, and that the values of $K$ (see Seely, Advanced Mechanics of Materials, p. 144) for different ratios of the length of the sides $a$ and $b$ were about as follows:

| $b/a$ = | 0 | 0.2 | 0.4 | 0.6 | 0.8 | 1.0 |
|---|---|---|---|---|---|---|
| $K$ = | 0.63 | 0.62 | 0.56 | 0.48 | 0.40 | 0.32 |

Timoshenko and Lessells (Applied Elasticity) give an analysis which shows that the maximum moment at the center of the plate, in strips of unit width through the center of the plate, parallel to the short and long sides respectively, when the sides are simply supported, and the load is $w$ lb. per sq. in., uniformly distributed over the plate, is given by the equations

$$M_{1\,\max.} = K_1 wb^2 \qquad [20a]$$

$$M_{2\,\max.} = K_2 wb^2 \qquad [20b]$$

The approximate deflection $y$ is given by

$$y_{\max.} = Dwb^4/Et^3 \qquad [21]$$

where $t$ = thickness, in.; $E$ = modulus of elasticity; $K_1$, $K_2$, and $D$ are constants given in Table 4.

For rectangular plates with the edges fixed, the maximum deflection is given by the same equation as for the plates with supported edges, but with constant $D$ as follows, and Poisson's ratio being taken as 0.3:

| $a/b$ | 1.00 | 1.25 | 1.50 | 1.75 | 2.00 | ∞ |
|---|---|---|---|---|---|---|
| $D$ | 0.0138 | 0.0199 | 0.0240 | 0.0264 | 0.0277 | 0.0284 |
| $K$ | 0.0513 | 0.0665 | 0.0757 | 0.0817 | 0.0829 | 0.0833 |

The maximum bending moment in a strip of unit width is at the middle of the longer

**Table 5.—Formulas for Bending Moments in Rectangular Flat Slabs**

Values are per unit width. Poisson's ratio = 0, $a$ = longer side, $b$ = shorter side, $\alpha = b/a$

| | | Moments in Span $b$ | | Moments in Span $a$ | |
|---|---|---|---|---|---|
| | | At center of edge | At center of slab | At center of edge | At center of slab |
| Rectangular Slabs | Four edges simply supported | 0 | $\frac{1/8\ wb^2}{1 + 2\alpha^3}$ | 0 | $\frac{wb^2}{48}(1 + \alpha^2)$ |
| | Span $b$ fixed; span $a$ simply supported | $\frac{1/12\ wb^2}{1 + 0.2\ \alpha^4}$ | $\frac{1/24\ wb^2}{1 + 0.4\ \alpha^4}$ | 0 | $\frac{wb^2}{80}(1 + 0.3\ \alpha^2)$ |
| | Span $a$ fixed; span $b$ simply supported | 0 | $\frac{1/8\ wb^2}{1 + 0.8\ \alpha^2 + 6\alpha^4}$ | $\frac{1/8\ wb^2}{1 + 0.8\ \alpha^4}$ | $0.015\,wb^2\left(\frac{1 + 3\alpha^2}{1 + \alpha^4}\right)$ |
| | All edges fixed | $\frac{1/12\ wb^2}{1 + \alpha^4}$ | $\frac{1/8\ wb^2}{3 + 4\alpha^4}$ | $1/24\ wb^2$ | $0.009\,wb^2(1 + 2\alpha^2 - \alpha^4)$ |
| Elliptical slab with fixed edges; diameters $a$ and $b$; $b/a = \alpha$ | | $\frac{1/12\ wb^2}{1 + 2/3\ \alpha^2 + \alpha^4}$ | $\frac{1/24\ wb^2}{1 + 2/3\ \alpha^2 + \alpha^4}$ | $\frac{1/12\ wb^2\ \alpha^2}{1 + 2/3\ \alpha^2 + \alpha^4}$ | $\frac{1/24\ wb^2\ \alpha^2}{1 + 2/3\ \alpha^2 + \alpha^4}$ |

fixed side and is equal to $M_{\max} = Kwb^2$, $K$ being as given above, and $a$ and $b$ being the lengths of the long and short sides respectively.

Professor Westergaard in a study of reinforced-concrete slabs supported on columns has computed the moments in medium-thick rectangular and elliptical plates (*Proc. A.C.I.*, 1921). These are plates in which there is neither an appreciable absorption of energy by the vertical shearing stresses nor by the stretching of the middle plane of the plate. By means of a number of simplifying assumptions the values for the moments as given in Table 5 were found.

## 3. STRESSES IN SOLIDS UNDER PRESSURE

**CYLINDRICAL AND SPHERICAL ROLLERS.**—Approximate equations for areas of contact and pressures have been worked out for a number of cases (Timoshenko and Lessells' Applied Elasticity). These are given in Table 6.

**HERTZ EQUATIONS.**—A general mathematical solution of the problem of the stresses produced by the pressure of one solid upon another, of which cylindrical and spherical rollers are a special case, was made by H. Hertz (English translation in Miscellaneous Papers by H. Hertz). The Hertz equations are very complex and deal only with surface stresses. Thomas and Hoersch (*Bull.* 212, Engg. Exp. Sta., University of Illinois, 1930), as a part of an investigation of railroad rails and the development of transverse fissures in them, extended the Hertz equations to a study of the shearing stresses within the solid. They developed methods, too long to be given here, of computing the magnitude

**Table 6.—Areas of Contact and Pressures with Two Surfaces in Contact**

Poisson's ratio = 0.3; $P$ = load, lb.; $P_1$ = load per in. of length, lb.; $E$ = modulus of elasticity

| Character of Surfaces | Maximum Pressure, $s$, at Center of Contact, lb. per sq. in. | Radius, $r$, or Width, $b$, of Contact Area, in. |
|---|---|---|
| Two spheres  | $s = 0.616\sqrt[3]{PE^2\left(\frac{d_1+d_2}{d_1\,d_2}\right)^2}$ | $r = 0.881\sqrt[3]{\frac{P}{E}\left(\frac{d_1\,d_2}{d_1+d_2}\right)}$ |
| Sphere and plane  | $s = 0.616\sqrt[3]{\frac{PE^2}{d^2}}$ | $r = 0.881\sqrt[3]{\frac{Pd}{E}}$ |
| Sphere and hollow sphere  | $s = 0.616\sqrt[3]{PE^2\left(\frac{d_2-d_1}{d_1\,d_2}\right)^2}$ | $r = 0.881\sqrt[3]{\frac{P}{E}\left(\frac{d_1\,d_2}{d_2-d_1}\right)}$ |
| Cylinder and plane  | $s = 0.591\sqrt{\frac{P_1\,E}{d}}$ | $b = 2.15\sqrt{\frac{P_1\,d}{E}}$ |
| Two cylinders  | $s = 0.591\sqrt{P_1\,E\left(\frac{d_1+d_2}{d_1\,d_2}\right)}$ | $b = 2.15\sqrt{\frac{P_1}{E}\left(\frac{d_1\,d_2}{d_1+d_2}\right)}$ |

and location of the maximum shearing stresses produced in solids under pressure, such as in railroad rails under a wheel load. They have obtained experimental verification of the correctness of their equations by a "strain-etch" method, but point out that the mathematical equations derived do not hold except for thick material and where the ratio of the length of contact to the width of contact is large.

In a cylinder of radius $R$, in., under a load $P'$, lb. per in. of length, on a plane, assuming Poisson's ratio as $1/4$ the maximum shearing unit stress $s_s = 677\sqrt{P'/R}$, the width of contact equals $0.000564\sqrt{P'R}$, the depth to the point of maximum shear is $0.000222\sqrt{P'R}$, and the maximum intensity of pressure is $2256\sqrt{P'/R}$. In the case of crossed cylinders, the empirical equation is

$$s_s = 11{,}750\,P^{1/3}/(R_1/R_2)^{0.271}R_2^{2/3} \qquad [22]$$

where $R_1$ = radius of larger cylinder; $R_2$ = radius of smaller cylinder; $P$ = total pressure, lb., between the two solids; the ratio $R_1/R_2$ is only true within the limits of 1 and 8. Table 7 gives a number of values computed by the methods of Thomas and Hoersch.

Stribeck made extensive experiments on ball bearings in 1898–1900, and his reports are translated in *Trans.* A.S.M.E., vol. xxix, p. 421.

**Table 7.—Shearing Stresses in Solids under Pressure**

| Case | Radius, $R_1$, in. | Length of Cylinder, in. | Radius, $R_2$, in. | Load, lb. | Area in Contact, sq. in.* | Maximum Shearing Stress, lb. per sq. in. | Depth below Surface of Point of Maximum Shearing Stress, in. |

* Computed by approximate equation

Where rollers are moving, as at the end of a truss or girder or with a rolling lift bridge, under relatively high pressures, the plate on which the roller rests is the critical part. The metal of the plate tends to flow longitudinally under the backward and forward motion. Wilson (*Bull.* 191, Engg. Exp. Sta., University of Illinois, 1929) reports on experiments with rollers of the size used in rolling lift bridges, between 116 in. and 476 in. radius, and concludes that the bearing capacity of a plate depends upon its thickness, the tensile strength of the material, and the diameter of the roller. He proposes the formula

$$P = (12{,}000 + 80\,D)\{p - 13{,}000)/23{,}000\} \qquad [23]$$

where $P$ = safe working load, lb. per in. width of plate; $D$ = diameter of roller, in.; $p$ = yield point strength of the material in tension, lb. per sq. in. The thickness of plate, in., should not be less than $(1.0 - 0.004\,D)$ with $D$ not less than 120 in. Steel bridges usually have one end on rollers to allow for expansion. The usual allowable load for expansion rollers is $P = 600\,D$; $P$ = load, lb. per lineal inch of roller, and $D$ = diameter of roller, in.

# TESTING OF MATERIALS

## 1. EQUIPMENT

**TESTING MACHINES.**—Machines for testing material are of varying construction and capacity, for testing specimens in tension, in compression, in torsion and for other specific purposes. Usually the mechanism for applying the load to the specimen is independent of the weighing apparatus. By this arrangement the accuracy of the weighing is not affected by the deformation of the specimen which takes place as the load is applied. In machines for testing bars in tension or compression, the ends of the test-piece are fastened in the two heads of the machine One of the heads is moved by screws, driven by a train of gears, causing a gradually increasing stress in the test-piece. Some machines are built so that the head is moved by hydraulic pressure, but the revolving screw construction is more common in the United States, although the use of hydraulic pressure machines is increasing rapidly (1937).

**THE COMPOUND LEVER MACHINE** derives its name from the weighing mechanism. The load may be applied by revolving screws or by hydraulic pressure. In either case, the tension or compression acting on the test-piece is transformed into a downward force bearing on a platform resting on levers equipped with hardened steel knife edges and arranged like those in a platform scale. The force acting on the platform is transmitted through the levers to a graduated scale beam which is balanced by a poise to give the load on the test-piece.

**The Screw-power Compound Lever Testing Machine (Olsen or Riehlé Machines)** is the type in most common use in the U. S. Power is supplied by a belt drive or by a direct-connected motor, and is transmitted through a series of gears to vertical screws which operate the crosshead of the machine. The force applied by the belt, multiplied many times by the gearing and the screws, is applied to the test specimen by the crosshead. Tension specimens are placed between the crosshead and the upper head of the testing machine. Compression specimens or cross-bending specimens are placed between the crosshead and the weighing table. As the crosshead moves downward, the specimen transmits downward pressure to the weighing table, which is supported on compound levers fitted with knife-edge bearings. These compound levers transmit the force, reduced, to a simple lever, which, in turn, transmits it still further reduced, to the weighing beam. As the load is applied the beam is kept in balance by moving the poise. The position of the latter, with the beam in balance, indicates the load on the specimen. These machines are built by Tinius Olsen Co., Philadelphia, and Riehlé Bros. Testing Machine Div. of American Machine & Metals, Inc., New York.

**THE DIRECT-ACTING HYDRAULIC MACHINE** has a head moved by hydraulic pressure, the intensity of which is read on a pressure gage. The load on the test-piece is determined by multiplying the pressure reading by a constant which depends on the area of the cylinder. Due to variations in the plunger friction, these machines are not adapted for accurate testing of small specimens, but are used to advantage in tests requiring big loads to rupture the specimen, and where slight variations in accuracy are permitted.

**The Amsler Machine** is a machine of the hydraulic type built in Schaffhausen, Switzerland, which has considerable use in the U. S. A plunger moving in a cylinder near the top of the machine raises and lowers a rigid framework with respect to a fixed tension head at the bottom and a fixed compression head at the top of the machine. Oil is pumped into the cylinder to move a plunger around to fit the cylinder. This renders packing unnecessary and eliminates a main source of error in the hydraulic machine. A plunger in a branch line from the main cylinder to a smaller one actuates a pendulum weight by means of a projecting arm. This displacement of the pendulum rotates a pointer on a dial from which the load is read directly. The Amsler machine can be handled by a single observer.

**The Emery-Tatnall Machine** is a hydraulic machine in which the load is applied through a plunger moving in a cylinder under oil pressure. The distinctive feature is the load-weighing device, called a weighing capsule. This is not connected to the load-applying mechanism, and is unaffected by friction between cylinder and plunger. One of the testing heads rests on a thin flat diaphragm over a shallow recess filled with oil. A slight movement of the diaphragm decreases the volume of the recess and creates pressure on the oil, which is recorded on a gage calibrated to read the load. One precaution is necessary: the weighing capsule must be kept filled with oil to avoid recorded loads being seriously in error.

**VERIFICATION OF TENSION-COMPRESSION TESTING MACHINES.**—A.S.T.M. Tentative Standard, E4–34T, *Proc.* A.S.T.M. vol. xxxiv, Pt. 1, p. 1233, 1934, lists four methods of verifying testing machines, in the order of their accuracy, *viz.*:

**1. Standard Weights** are placed on the weighing mechanism of the testing machine. This is the most accurate method but has the following limitations: (*a*) only a limited range of load can be covered; (*b*) non-portability of standard weights; (*c*) not applicable to horizontal testing machines.

**2. Proving Levers.**—These are simple levers whose fulcrums bear on the weighing platform; knife-edges on the short arms of the levers bear on the crosshead of the machine. At the ends of the long arms of the levers, standard weights are hung so that, from the ratio of the arms, the force acting on the weighing table may be computed. The range of load possible with this method is greater than that of the standard weights method, but it is not great enough for very large testing machines.

**3. Elastic Calibration Device** which consists of an elastic member, which previously has been calibrated by noting the deformation at a series of loads. For a primary standard, the loads should be obtained by dead weights or proving levers. When verifying a testing machine, load is applied to the device by the machine to be tested and the deformation noted. The difference between the load reading on the machine under test and the actual load, as determined for the observed deformation from the calibration curve of the device, represents the error in the machine being verified.

**4. Comparison Method.**—A series of test specimens (" companion specimens ") cut from the same piece of metal are necessary. Half of the specimens are tested in a machine

**Table 1.—Large Testing Machines in United States**

(All are of the hydraulic type)

| Place | Date Installed | Capacity, lb. | Type | Length of Maximum Specimen, ft.* |
|---|---|---|---|---|

* The maximum length of tension specimen will depend on the amount of elongation which must be provided for before failure occurs.

which has been verified by one of the above methods, and the other half in the machine under test. The difference in load reading for the same deformation, between the two machines, is the error in the machine being tested. This method should be used only when none of the other methods above may be applied.

**FLEXURE TESTS.**—The regular tension-compression testing machines are used for flexure tests by arranging the specimen so that the end supports bear on the weighing table, as shown in Fig. 1.

**TORSION TESTING MACHINES.**—In Prof. Thurston's machine, invented in 1872, the specimen is held horizontally with its ends secured in two spindles. One of these spindles is rotated by power. The other spindle is connected to a pendulum carrying a heavy weight which resists the turning force as it deviates from its vertical position, thus producing a torque whose magnitude is shown by a gage or dial.

Power torsion machines are built so that the two ends of the specimen are held in rotating chucks. The power is applied at any desired speed by gearing connected to one of the chucks. The chuck at the other end is prevented from rotating by a system of levers connected to a scale beam which is balanced by a poise. The position of the poise indicates the twisting moment in in.-lb.

**IMPACT TESTS.**—The essential parts of an impact testing machine are: a moving weight which strikes the specimen with sufficient kinetic energy to cause fracture; an anvil or block on which the specimen is supported; a device for measuring the kinetic energy of the moving weight after it has broken the specimen.

**Drop-weight Machines.**—The impact is obtained by a hammer of known weight falling from a predetermined height on the specimen. In the Freemont machine the loss of kinetic energy in the hammer due to impact is obtained by having the weight, after breaking the specimen, strike a platen placed on calibrated springs, and measuring the downward movement of the platen against the resistance of the springs. Another method is used in the Hatt-Turner machine, in which a brass stylus is attached to the falling hammer; during impact the stylus is forced by a spring against a sheet of metallized paper mounted on a drum which rotates about its vertical axis, thus causing a curve to be plotted. The speed of the drum is determined from a second curve plotted on the metallized paper by a stylus fastened to one prong of a tuning fork. From the two curves the changes in velocity of the hammer as well as the stress-deformation relations may be calculated.

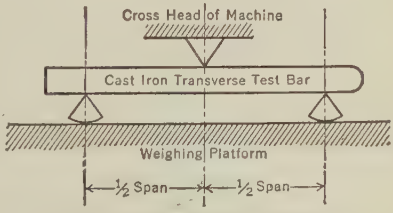

Fig. 1. Arrangement for Flexure Test

**The Charpy Pendulum Machine** is used for testing small notched specimens which are placed horizontally, with the ends supported by the anvil. The hammer strikes the specimen midway between the supports opposite the notch, and after breaking the specimen continues its swing upward. The energy used in breaking the specimen is the product of the weight of the pendulum and the difference between its height of fall and height of rise.

**The Izod Machine** is used for testing a notched specimen supported at its lower end in a vertical position as a cantilever; the pendulum strikes the specimen at a definite distance above the notch. See Energy or Dynamic Loads, p. 7–15.

**REPEATED STRESS TESTING MACHINE.**—The following types of machines are available for producing reversed bending: The Upton-Lewis for flat specimens; the short-specimen rotating beam; the long-specimen rotating beam; and the cantilever rotating beam. Only the long-specimen machine (sometimes known as the Sondricker or Farmer type) is here described. It consists of two rings or collars, rotating in a cage of ball bearings, for supporting the specimen which is 0.40 in. diameter and 13 in. long. The specimen is rotated by a motor; the number of revolutions is recorded by a counter attached to one end of the specimen. Suspended weights load the beam at two points. These act through ball bearings to produce a uniform bending moment over the central portion of the specimen. The number of cycles of completely reversed stress equals the number of revolutions. The speeds commonly used are from 1000 to 2000 r.p.m.

**EXTENSOMETERS.**—Several types of extensometers are used to measure elongation within the elastic limit during a test. In general, they comprise clamps which grip the test-piece at the gage marks and a micrometer or Ames dial to measure the distance between the clamps, which increases as the load is applied. With some extensometers, elongations thus may be measured to the nearest 0.0001 inch.

## 2. STANDARD TEST-PIECES

The results obtained in a test on material are affected by the method of testing and the size and shape of the specimen. Standards have been adopted by the A.S.T.M., the A.S.M.E. and various associations of manufacturers, to eliminate variations in results due to these causes. The standards of the A.S.T.M. are summarized below.

**SPECIMENS FOR TENSION AND BEND TESTS.**—(Extracts from Specifications A7–36, A9–36, A10–34, A113–33 for Structural Steel for Bridges, Buildings, Locomotives, etc., A.S.T.M. Standards, 1936). *a.* Test specimens shall be prepared for testing from the material in its rolled or forged condition, except that the specimens for annealed material shall be prepared from the material as annealed for use, or from a short length of a full section similarly treated; the specimen for rivet bars which have been cold drawn shall be normalized before testing. *b.* Test specimens shall be taken longitudinally and, except as noted in *c*, *d* and *e*, shall be of the full thickness or section of the material as rolled. For plates, shapes and flats the specimens may be machined to the form and dimensions of Fig. 2 or with both edges parallel. *c.* Tension test specimens for material over 1 1/2 in. thickness or diameter, except pins and rollers, may be machined to a thickness or diameter of at least 3/4 in. for a length of at least 9 in., or they may conform to the dimensions shown in Fig. 3. *d.* Bend test specimens for material over 1 1/2 in. thickness or diameter, except pins and rollers, may be machined to a thickness or diameter of at least 3/4 in. or to 1 × 1/2 in. in section. *e.* Tension test specimens for pins and rollers shall be taken so that the axis is 1 in. from the surface and shall conform to the dimensions shown in Fig. 3, while bend test specimens shall be 1 × 1/2 in. in section. *f.* The machined sides of rectangular bend specimens may have the corners rounded to a radius not over 1/16 in.

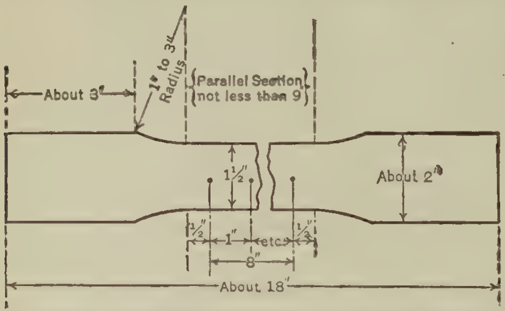

FIG. 2. Tension Test Specimen, 8-in. Gage Length

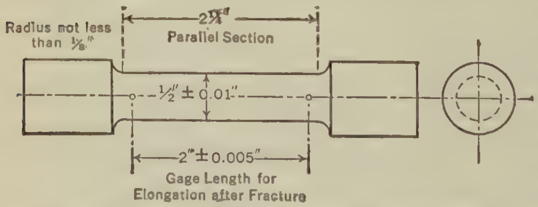

FIG. 3. Tension Test Specimen, 2-in. Gage Length

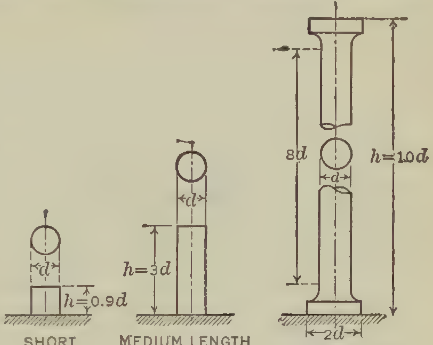
**SPECIMENS FOR COMPRESSION TESTS.**—A.S.T.M. Tentative Standards (1934) E9–34T recommends cylindrical specimens with plane ends, of the form shown in Fig. 4. The short specimen, Fig. 4*a*, is recommended for tests of bearing metals, or similar metals, which in service are in the form of a thin plate or shell, and which carry the load perpendicular to the surface. Medium length specimens, Fig. 4*b*, are recommended for tests to determine the general compressive strength qualities of metallic materials. Long specimens, Fig. 4*c*, are recommended for determining the modulus of elasticity in compression of metallic materials. Suggested diameters, with a tolerance of +0.01 in., are as follows: Short specimens, 1 in.; medium length specimens, 0.798 in., 1 in., and 1 1/8 in.; long specimens, 1 1/4 in. Dimensions of the test specimens should be given in reports of compression tests.



SHORT SPECIMEN (*a*) MEDIUM LENGTH SPECIMEN (*b*) LONG SPECIMEN (*c*)

FIG. 4. Compression Test Specimens

**SPECIMENS FOR IMPACT TESTS.**—A.S.T.M. Tentative Standard, 1934, E23–34T recommends the test specimens shown in Figs. 5*a* and 5*b* for use in Charpy type and Izod type impact machines, respectively.

FIG. 5. Impact Test Specimens

## 3. PRECAUTIONS REQUIRED IN MAKING TESTS

**1. Inspection of Specimen.**—Examine the specimen for defects or irregularity of form. It should be of uniform section between gage marks on which measurements of elongation are to be made. The distance between gage marks, which usually is 8 in., should be marked off into half-inch divisions.

**2. Placing Specimen in Machine.**—The test-piece should be placed in an axial position, that is the line of stress of the machine should be in line with the axis of the specimen. Care should be taken to see that the ends of the specimen are properly gripped in the heads of the machine. When wedges are used, the full length of the wedge should bear against the ends of the specimen. The extensometer should be placed in position so that the clamps are at the gage marks and the specimen centered on the instrument.

**3. Speed of Testing.**—Regard must be had to the time occupied in making tests of certain materials. Wrought iron and soft steel can be made to show a higher strength than their actual apparent strength by keeping them under strain for a great length of time. A.S.T.M. Standard, E8–36, 1936, points out that the values of the yield point and ultimate strength may be increased by operating the testing machine at too high speed, and it recommends that the speed of the head of the testing machine shall be such that the load can be accurately weighed. In determining yield strength, the crosshead speed for the 2-in. gage length shall not exceed 0.125 in. per min.

In testing soft alloys, copper, tin, zinc, and the like, which flow under constant stress, their highest apparent strength is obtained by testing them rapidly. In recording tests of such materials the length of time occupied in the test should be stated.

**4. Increment of Load.**—A.S.T.M. Standard E8–33 suggests the following method for choosing increments in a tension test. An increment of load, about 1/10 of the estimated load corresponding to the knee of the stress-deformation diagram, is applied and the corresponding change of reading, Δ, of the extensometer noted. For the remainder of the test, the increments of load are made such that the extensometer readings change by approximately Δ.

## 4. INTERPRETATION OF TEST RESULTS

**DATA OBTAINED FROM TENSION TEST.**—The following data usually are obtained in testing by tension in a testing-machine a sample of a material:

*a.* The load at the elastic limit or yield point, lb.

*b.* The maximum load applied before rupture, lb.

*c.* The elongation of the piece, measured between gage points placed a stated distance apart before the test, usually 8 in. or 2 in.

*d.* Sometimes the area at the point of fracture.

The data now calculated are: 1. Tensile strength, lb. per sq. in. of original area; 2. Percentage elongation; 3. Elastic limit or yield point, lb. per sq. in. The modulus of elasticity is calculated either from the stress-strain graph, or as the ratio of the unit stress within the elastic limit to the corresponding unit strain. Due to the difficulty of making accurate measurements of the fractured area of a test piece and to the fact that elongation is more valuable than reduction of area as a measure of ductility, of toughness, or of energy absorbed before rupture, reduction in area frequently is not reported.

**Determination of Yield Point.**—Two methods for determining yield point of metals that have a " sharp knee " stress-deformation diagram are:

**1. " Drop of the Beam " Method.**—Load is applied to the specimen at a steady rate of increase, the beam being kept in balance by running out the poise. At the yield point the increase of load ceases temporarily, but the operator, running out the poise at a uniform rate, runs it a trifle beyond the balance position, and the beam of the machine drops for a brief, but appreciable, interval of time. In a machine fitted with a self-indicating weighing device there is a sudden halt in the motion of the load-indicating pointer, corresponding to the drop of the beam. The load at the " drop " or the " halt " is noted and the corresponding unit stress reported as the yield point.

**2. Total Deformation Method Using Dividers.**—An observer with a pair of dividers watches for visible elongation between two gage marks on the specimen. When visible stretch is observed the load is noted and the corresponding unit stress reported as the yield point.

**DETERMINATION OF YIELD STRENGTH.**—For determining yield strength, A.S.T.M. Standard E8–33, 1933, gives two methods:

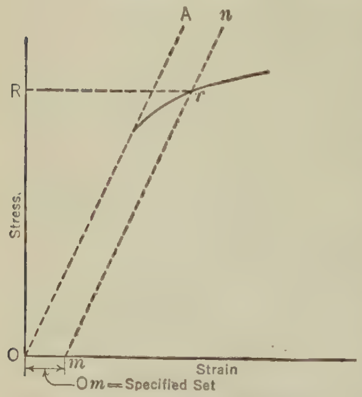

Fig. 6 Stress-deformation Diagram

**1. The Set Method.**—This method can be used, if desired, for materials having sharp-knee stress-deformation diagrams, but is especially adapted to materials whose stress-deformation diagram in the yield range is a smooth curve of gradual curvature.

For nearly all materials, if at any point on the stress-deformation diagram, such as $r$, Fig. 6, the load is released, the diagram for decreasing load will follow a line, $rm$, approximately parallel to the initial portion, $OA$, of the diagram for increasing load. $Om$ then is the approximate value of the permanent set after release of stress $OR$. The value of $Om$ is given in percentage of original gage length. Thus, to determine yield strength by the set method, it is necessary to secure data (autographic or numerical) from which a stress-deformation diagram may be drawn. Then with the stress-deformation diagram (Fig. 6) lay off $Om$ equal to the specified value of the set, and draw $mn$ parallel to $OA$ and thus locate $r$, the intersection of $mn$ with the stress-deformation curve. Draw $Rr$ parallel to the X-axis. $OR$ is the yield strength.

In reporting values of yield strength obtained by this method, the specified value of " set " used should be stated in parentheses after the term yield strength. Thus:

Yield strength (set = 0.1%) = 52,000 lb. per sq. in., indicates that, at a stress of 52,000 lb. per sq. in., the approximate permanent set of the material reached the value of 0.1% of the original gage length. (A value of 0.20% of the gage length has been used rather widely for metals.)

In using this method, an extensometer reading to 0.0001 in. per in. of gage length would be sufficiently sensitive for most materials. It will be observed that elastic limit and proportional limit are special values of yield strength, in which the specified limiting set is not measureable with the instruments used, and hence is considered to be zero.

**2. Approximate Method without Stress-deformation Diagram.**—For tests to determine the acceptance or rejection of material, whose stress-deformation characteristics are known from previous tests of similar material in which stress-deformation diagrams were plotted, the total deformation corresponding to the stress at which the specified permanent set occurs will be known within satisfactory limits; therefore, in such tests a specific total deformation may be used, and the stress on the specimen, when this total deformation is reached, is the value of the yield strength. The total deformation can be obtained satisfactorily by an extensometer, or in some cases by dividers, particularly if the surface of the specimen is so prepared that the line made by the dividers is a fine one, and if it is observed through a magnifying glass. This approximate method is recommended for use only after agreement between producer and consumer, with the understanding that check tests be made to obtain stress-deformation diagrams for use with the Set Method to settle any misunderstandings.

**DETERMINATION OF TENSILE STRENGTH (ULTIMATE).**—The tensile strength of a material is determined by dividing the maximum load carried in a tension test by the original area of cross-section of the specimen. It is important that the speed of testing should not be so high as to render uncertain the balancing of the beam of the testing machine, or to cause "surging" of a self-indicating load-measuring device.

**DETERMINATION OF ELONGATION AFTER FRACTURE** (A.S.T.M. Standard E8–33, 1933).—Measurement of elongation after fracture of tension test specimens can be made with sufficient accuracy by means of a pair of dividers and a scale. The elongation should not be reported for any tension test specimen which breaks outside the middle third of the gage length.

NOTE. If only a few specimens are available for testing, it is recommended that, in marking the gage length for measuring elongation after fracture, it be divided into eight parts (see Fig. 7), and that, if a specimen breaks inside the gage length but outside the middle third of the gage length, the requirement in the foregoing paragraph be waived, and the elongation be measured and reported as follows:

1. If specimen breaks in the middle half of the gage length (between *C* and *G*), elongation is measured directly over the stretched gage length. 2. If specimen breaks between *A* and *C* (or between *G* and *I*) but nearer *B* than *A* (or nearer *H* than *I*), elongation from *A* to *C* (or from *G* to *I*) is measured, and to this is added *twice* the measured elongation from *C* to *F* (or from *D* to *G*). 3. If specimen breaks within one-half a division of an end gage mark, the elongation from *A* to *E* (or from *E* to *I*) is measured and multiplied by 2. The above method can be applied to specimens of any gage length, to both turned and flat specimens, but is not applicable to brass specimens.

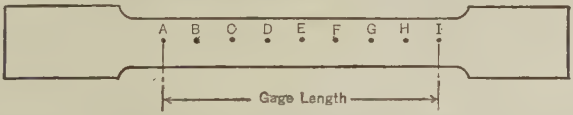

FIG. 7.—Method of Marking Gage Length for Measuring Elongation after Fracture

**DETERMINATION OF REDUCTION OF AREA.**—The measurement of reduction of the dimensions of a specimen after fracture may be made by the direct measurement with a micrometer of the smallest cross-section of the specimen. For round specimens this measurement best can be made by holding the broken pieces together in a vise or between centers and measuring the average diameter of the smallest section, using a micrometer fitted with rather sharp points. Reduction of area is calculated as the percentage reduction, based on original area.

**COMPRESSION TEST.**—The methods used to determine elastic limit, proportional limit, yield point, and yield strength in compression tests are, in general, the same as those used in tension tests. Compressive strength is determined by dividing the maximum load by the original area of cross-section of the specimen.

In a material which fails in compression with a shattering fracture, compressive strength has a very definite value. In materials which do not fail by a shattering fracture, the value obtained for compressive strength is an arbitrary value, depending on the degree of distortion which is regarded as indicating complete failure of the material.

## 5. MISCELLANEOUS TESTS

**PROOF TESTS.**—A proof test is one in which a part or machine, as a whole, is subjected to a load which equals or exceeds the design or working load but which does not test the part to destruction; for example, the hydrostatic test of cast-iron pipe at the foundry, where the pipe is subjected to a water pressure of about twice the normal working pressure.

**SHORT TIME TESTS FOR ENDURANCE LIMIT.**—Since the determination of the endurance limit for any given steel or metal takes considerable time, attempts have been made to devise short-time tests which will give, at least, some indication of the probable endurance limit. No method has been found which is entirely satisfactory or which has been generally accepted. Two methods have shown some promise of success, *viz.*, 1. The rise-in-temperature method; 2. The electrical resistance method.

**Rise-in-temperature Method.**—(Moore and Kommers, *Bull.* No. 124, Engg. Exp. Sta., Univ. of Ill., 1921). A standard rotating beam specimen is held at one end and, by an eccentric movement of the other end, a bending stress is produced in a manner similar to that obtained when the beam is rotated. A thermocouple is attached to the specimen at the section of greatest stress and connected to a galvanometer. The specimen is run at 1000 r.p.m. for 30 sec. at stresses which increase by stages; a reading of the galvanometer is taken for each value of the stress. The stress at which there is a sudden increase in the reading of the galvanometer is taken as the endurance limit. For ferrous metals the results varied from 14% below those found by the standard method to 18% above, but in the main they were within 5 or 6% of the standard values. The test does not give consistent results with non-ferrous metals.

**Electrical Resistance Method.**—This sometimes is known as the Ikeda method, after the Japanese who developed it. (See Moore and Konzo, *Bull.* 205, Engg. Exp. Sta., Univ. of Ill., 1930.) It consists in determining the electrical resistance corresponding to various stresses and noting a sudden change in the resistance. The stress where the change occurs in taken as the endurance limit. The method gives results comparable with those obtained by the rise-in-temperature method and gives consistent results with non-ferrous metals. It requires delicate instruments and careful manipulation.

**CREEP LIMIT TESTS.**—The following description of the apparatus for and the method of making creep tests is abstracted from Norton, The Creep of Metals at High Temperatures (McGraw-Hill, New York). Specimens 0.505 in. diam. with a 4-in. gage length are placed in an electric furnace. The load is applied by weights and a lever having a ratio of 10 to 1. The furnace, which holds 5 or 6 specimens at one time, is a hollow cylinder wrapped with asbestos paper and a heating coil which maintains a constant temperature through a regulating device. The extension of each specimen is measured by means of a dial connected to the lever arm which applies the load. To prevent oxidation of the specimen, a stream of nitrogen is introduced at the bottom of the apparatus.

The specimens are loaded nearly to the estimated creep limit for a given temperature, and this load is maintained for 400 hours, the elongation being measured twice a day. The load then is increased 10% and maintained for 400 hours, the elongation again being measured twice a day. This rate of increase in load is continued until the creep becomes large. Thus for each temperature, there will be a series of stress-elongation readings. A graph is plotted for each stress, with time as abscissa and percentage of elongation as ordinate. This usually is a straight line. The slopes of these time-percentage elongation lines are next plotted against stress in logarithmic paper. There will be one line for each temperature and, since the points fall on a straight line, the stress corresponding to any given rate of creep may be read directly from the graph. Rapid progress is being made (1937), in the development and revision of standard methods of creep limit tests. The latest issue of the A.S.T.M. standards should be consulted.

**X-RAY EXAMINATION OF CASTINGS AND FORGINGS.**—When x-rays are passed through castings or forgings which contain defects, the x-rays pass through the defects more rapidly than through the sound metal and thus outline the defects on a photographic plate.

The x-ray examination of castings or forgings has two functions: 1. Development of manufacturing technique; 2. Inspection of the finished product. In Recommended Practice for Radiographic Testing of Metal Castings (A.S.T.M. Standards, E15–29) the following defects are enumerated as being capable of detection by x-ray methods: Gas cavities, slag inclusions, sand inclusions, pipe cavities, porosity, cracks, metal segregation. Since there are no standards governing the number, extent and character of defects, no specific requirement can be laid down, but if the defects are known to be present the user can judge of their probable effect and act accordingly.

**Equipment.**—Equipment needed for x-ray examination consists of an x-ray tube, transformers, photographic apparatus, and a lead-lined operating chamber. The part to be examined is placed between the x-ray tube and the photographic film and an exposure made for the proper length of time. Since x-rays are very dangerous it is imperative that the operator be properly protected from them by lead-lined boxes or chambers. The operation is one requiring expensive apparatus and skilled technique, but it is very satisfactory for castings in which a positive knowledge of their soundness is essential. For metal not over 3 $^1/_2$ in. thick, a 200-kv. 8-milliampere Coolidge x-ray tube will be satisfactory. The Babcock & Wilcox Co. installed in 1933 a 300-kv., 10 milliampere tube for examining welded joints in pressure vessels (see Welding, p. 2–48). For detailed information see George L. Clark, Applied x-Rays (McGraw-Hill, New York); *Metals and Alloys;* St. John and Isenburger, Industrial Radiography (John Wiley & Sons, New York).

**SPECIAL TESTS** of materials, structures, and machines often are made to determine some particular characteristic. Typical tests of this character are given in Table 2. Other special tests are discussed below.

**Determination of Physical Properties from Magnetic Permeability.**—Tests of magnetic permeability of steel and iron seem to give some indication of the hardness, strength, and uniformity. They possess the great advantage that the test does not destroy the sample tested, and hence may be made on the actual parts to be used. Magnetic tests as an indication of hardness or strength are not standardized (1937), but hold promise of future usefulness.

The variation of magnetic qualities in a bar or disc of metal has been used to locate small invisible flaws. (See J. A. Capp, *Proc.* A.S.T.M., vol. xxvii, Pt. II, p. 268, 1927.) This principle has been utilized in the construction of a device, known as the transverse fissure detector car, for locating transverse fissures in railroad rails.

**Tests of Strength of Wood** have not been standardized (1937) to an extent which allows their inclusion in specifications for timber, but compression tests, flexure tests, shearing tests, and impact tests frequently are made. Compression tests are made both

**Table 2.—Special Tests of Materials, Structures, and Machines**

| Structural part, machine part, structure, machine or material tested | Test | Measurements |
|---|---|---|
| Floor panel of building. . | Proof test with dead load, not to destruction. | Deflections, tensile and compressive deformations in beams and columns. |
| Bridge. . . . . . . . . . . . . . . | Proof test with dead load or with moving load. | Deflections, tensile and compressive deformations in various members. |
| Riveted joints. . . . . . . . . | Tests of samples to destruction. | Ultimate load, slip of rivets. |
| Rivets, metal plates. . . . | Shearing test of samples to destruction, using special shearing tools. | Ultimate load, results depend on hardness of shearing tools used. |
| Bolts. . . . . . . . . . . . . . . . | Tests of samples to destruction in tension or torsion. | Ultimate load. |
| Boilers. . . . . . . . . . . . . . . | Tests with hydrostatic pressure. Proof tests with pressures somewhat above working pressures. | Observation of leaks, cracks, or permenent distortion of parts. |
| Car couplers and coupler yokes | Proof tests, tests of samples to destruction under tension and impact tension. | Ultimate load, distortion under proof load. |
| Wire rope. . . . . . . . . . . . . | Tests of samples to destruction in tension. | Ultimate load, observation of manner of fracture. |
| Brake beams for railway cars. | Tests of samples to destruction in flexure. | Ultimate load, deflections. |
| Chain. . . . . . . . . . . . . . . . | Proof tests of entire chain in tension, tests to destruction of sample sections. | Set after removal of proof load, ultimate strength. |
| Large pipe. . . . . . . . . . . . | Hydrostatic pressure proof test. | Observation of leaks, cracks, or other evidence of failure. |
| Gear teeth. . . . . . . . . . . . | Scleroscope or Rockwell test for uniform hardness. | Hardness for various teeth. |
| Engraver's plates. . . . . . . | Brinell, Rockwell, or scleroscope tests for uniform hardness of samples. | Hardness at various points. |
| Strain insulators for electric transmission lines. | Proof load in tension, tension test of samples to destruction. | Evidences of failure under proof load, ultimate strength. |
| Eyebars. . . . . . . . . . . . . . . | Tension test of sample eyebars to destruction. | Yield point, ultimate load, stretch. |
| Columns. . . . . . . . . . . . . . | Compression tests of models or samples to destruction. | Yield point, ultimate load, deflection, axial compression. |

along the grain and across the grain. Compression specimens usually are rectangular blocks, and should be tested with spherical-seated bearing blocks. Wood has a rather poorly defined proportional limit in compression. In compression along the grain there is a well-defined ultimate strength. Shearing tests along the grain are made by the use of shearing blocks placed in the testing machine, or for larger specimens by testing short, deep beams. The shearing strength of wood along the grain is of great importance. Flexure tests both of small selected specimens and of large beams are common. In flexure tests the failure may be by longitudinal shear along the neutral axis, by compression along the upper side of the beam, or by tension along the lower side. Impact flexure tests show the shock-resisting qualities of wood. Hardness tests are made by using a steel ball 0.444 in. in diameter, and noting the load which causes the ball to penetrate to one-half its diameter.

**Impact Testing of Wood.**—The Turner-Hatt impact testing machine is in common use in the U. S. for impact testing of wood. It consists of an anvil on which the specimen is placed, and of a weight which can be dropped from various heights. Attached to the weight is a pencil which draws a record on a rotating drum. From this record the deflections of the specimen can be measured, as the weight is dropped from successively increasing heights until rupture occurs, or until the deflections increase abnormally, showing that the proportional limit has been passed. Another method of making an impact test consists in dropping the weight from such a height that the specimen is fractured by one blow. The pencil attached to the weight traces a curve on the rotating drum whose steepness is a measure of the velocity of the falling weight. By measuring the velocity of the weight before and after fracture of the specimen, the energy absorbed in fracturing the specimen can be determined. For detailed description of tests of timber, see the A.S.T.M. Standards, D143–27 and D198–27.

**DUCTILITY TESTS.—Ductility as Determined from Tension Test.**—The usual measures of ductility are the percentage of elongation and the percentage of contraction of area of a specimen in a tension test. Since the percentage elongation varies widely over the length of a tension specimen, the gage length over which the deformation is measured should be specified. A tension test for determining ductility is not suitable for many metals, for example, a thin metal specimen, which in tension usually fails without any appreciable elongation.

**Bending Test for Determining Ductility.**—A.S.T.M. standard specification A9–36, for bend tests on structural steel requires that bend test specimens shall stand being bent cold through 180° without cracking on the outside of the bent portion, around a pin, the diameter of which shall have the following relation to the thickness of the specimen:

| Thickness of Material | Ratio: $\frac{\text{Pin Diameter}}{\text{Thickness of Specimen}}$ |
|---|---|
| Up to 3/4 in., inclusive | 1 |
| Over 3/4 to 1 in., inclusive | 1 1/2 |
| Over 1 to 1 1/2 in., inclusive | 2 |
| Over 1 1/2 to 2 in., inclusive | 2 1/2 |
| Over 2 in. | 3 |

**Cupping Tests for Determining Ductility.**—For determining the relative ductility of thin sheet metal, the so-called cupping test often is used. Various machines are on the market for performing this test. In these, a spherical-ended plunger or ball is forced into the test specimen, which is held over a suitable die. For some machines, the maximum depth of the cup which can be formed is taken as a measure of ductility; for others, the measure of ductility is the load required to produce the cup, just as visible " necking down " occurs.

# MECHANISM AND MECHANICS

## ELEMENTS OF MACHINES

### 1. ELEMENTARY MACHINES

The object of a machine usually is to transform the work or mechanical energy, exerted at the point where the machine receives its motion, into work at the point where the final resistance is overcome. The specific result may be to change the character or direction of motion, as from circular to rectilinear, or *vice versa*, to change the velocity, or to overcome a great resistance by the application of a moderate force. In all cases the total energy exerted equals the total work done, the latter including the overcoming of all the frictional resistances of the machine as well as the useful work performed. No increase of power can be obtained from any machine, since this is impossible according to the law of conservation of energy. In a frictionless machine the product of the force exerted at the driving-point into the velocity of the driving-point, or the distance it moves in a given interval of time, equals the product of the resistance into the distance through which the resistance is overcome in the same time.

**ELEMENTARY MACHINES.**—The most simple machines, or elementary machines, are reducible to three classes, viz., the Lever, the Cord, and the Inclined Plane. The first class includes every machine consisting of a solid body capable of revolving on an axis, as the Wheel and Axle, or Crank. The second class includes every machine in which force is transmitted by means of flexible threads, ropes, belts, etc., as the Pulley.

The third class includes every machine in which a hard surface inclined to the direction of motion is introduced, as the Wedge, the Screw, the Cam, etc.

**THE EFFICIENCY OF A MACHINE** is a fraction expressing the ratio of the useful work to the whole work performed, which is equal to the energy expended. The limit to the efficiency of a machine is unity, denoting the efficiency of a perfect machine in which no work is lost. The difference between the energy expended and the useful work done, or the loss, usually is expended either in overcoming friction or in doing work on bodies surrounding the machine from which no useful work is received. Thus in an engine propelling a vessel, part of the energy exerted in the cylinder does the useful work of giving motion to the vessel, and the remainder is spent in overcoming the friction of the machinery and in making currents and eddies in the surrounding water.

**A LEVER** is an inflexible rod capable of motion about a fixed point, called a fulcrum. The rod may be straight, bent at any angle, or curved. It generally is regarded, at first, as without weight, but its weight may be considered as another force applied in a vertical direction at its center of gravity.

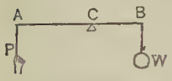

Fig. 1. 1st class

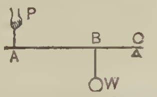

Fig. 2. 2nd class

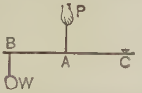

Fig. 3. 3rd class

Classes of Levers

The arms of a lever are the portions of it intercepted between the force, $P$, and fulcrum, $C$, and between the weight or load, $W$, and fulcrum. Levers are divided into three classes, according to the relative positions of the applied force, load, and fulcrum. In a lever of the first class, Fig. 1, the fulcrum lies between the points at which the force and the load act. In a lever of the second class, Fig. 2, the load acts at a point between the fulcrum and the point of application of the force. In a lever of the third class, Fig. 3, the point of application of the force is between the point of load and the fulcrum.

In all class of levers the relation between the force exerted, or the pull, $P$, and the load lifted, or resistance overcome, $W$, is expressed by the equation

$$P \times AC = W \times BC \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad [1]$$

where $AC$ is the lever-arm of $P$, and $BC$ is the lever-arm of $W$; or moment of the force = moment of the resistance.

In cases in which the direction of the force (or of the resistance) is not at right angles to the arm of the lever on which it acts, the "lever-arm" is the length of a perpendicular from the fulcrum to the line of direction of the force (or of the resistance). If $\alpha$ be the angle which the direction of the applied force $P$ makes with the lever arm, the effective force $P' = P \sin \alpha$ and

$$P' \times AC = P \sin \alpha AC = W \times BC \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [2]$$

Similarly the load $W$, acting at an angle $\beta$ to the lever arm would result in the equation

$$P \times AC = W \sin \beta \times BC \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [3]$$

or

$$P \sin \alpha \times AC = W \sin \beta \times BC \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [4]$$

The ratio of the resistance to the applied force is the inverse ratio of their lever arms or $W : P :: AC : BC$. Also if $V_w$ is the velocity of $W$, and $V_p$ is the velocity of $P$, then $W : P :: V_p : V_w$ and

$$P \times V_p = W \times V_w \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [5]$$

If $S_p$ is the distance through which the applied force acts, and $S_w$ is the distance through which the load is lifted, or through which the resistance is overcome, $W : P :: S_p : S_w$, and

$$W \times S_w = P \times S_p \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [6]$$

These equations are general for all classes of machines as well as for levers, it being understood that friction, which in actual machines increases the resistance, is not at present considered.

**The Bent Lever.**—In the bent lever, Fig. 4, the lever-arm of the weight $m$ is $cf$ instead of $bf$. The lever is in equilibrium when $n \times af = m \times cf$, but it is to be observed that the action of a bent lever may be very different from that of a straight lever. In the latter, so long as the force and the resistance act in lines parallel to each other, the ratio of the lever-arms remains constant, although the lever itself changes its inclination with the horizontal. In the bent lever, however, this ratio changes: thus, in the illustration, if the arm $bf$ is depressed to a horizontal position, the distance $cf$ lengthens while the horizontal projection of $af$ shortens, the latter becoming zero when the position of $af$ becomes vertical. As the arm $af$ approaches the vertical, the weight $n$ which may be lifted with a given force $s$ is very great, but the distance through which it may be lifted is very small. In all cases the ratio of the weight $m$ to the weight $n$ is the inverse ratio of the horizontal projection of their respective lever-arms.

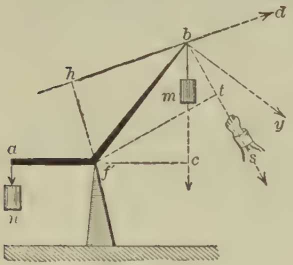

Fig. 4. Bent Lever

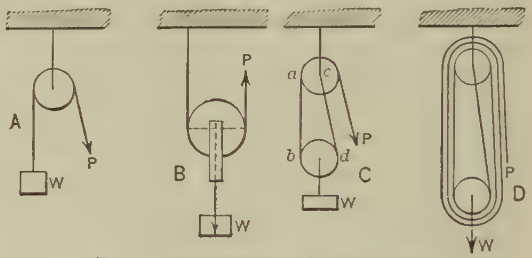

Fig. 5. Arrangements of Pulley Blocks

**THE CORD** is a flexible connector, used to change the direction of an applied force, usually by passing it over a pulley or wheel, or to transmit power from one source to another as in belt drives. For the application of the cord to power transmission, see pp. 24–14 to 24–52.

**Pulleys or Blocks.**—Let $P$ = force applied, or pull; $W$ = load lifted, or resistance. In the simple pulley $A$ (Fig. 5$A$), the point $P$ on the pulling rope descends the same amount that the load is lifted, therefore $P = W$. In Fig. 5$B$ and 5$C$ the point $P$ moves twice as far as the load is lifted, therefore, $W = 2P$. In Figs. 5$B$ and 5$C$ there is one movable block, and 2 plies of the rope engage with it. In Fig. 5$D$ there are 3 sheaves in the movable block, each with 2 plies engaged, or 6 in all. Six plies of the rope, therefore, are shortened by the same amount that the load is lifted and the point $P$ moves 6 times as far as the load; consequently $W = 6P$. In general, the ratio of $W$ to $P$ is equal to the number of plies of the rope that are shortened, and also is equal to the number of plies that engage the lower block. If the lower block has 2 sheaves and the upper 3, the end of the rope is fastened to a hook in the top of the lower block, then there are 5 plies shortened instead of 6, and $W = 5P$. If $V$ = velocity of $W$, and $v$ = velocity of $P$, then in all cases $VW = vP$, whatever the number of sheaves or their arrangement. If the hauling rope, at the pulling end, passes first around a sheave in the upper or stationary block, the direction in which the rope is led from this block to the point at which the pull on the rope is applied is immaterial; but if it first passes around the movable block, it is necessary that the pull be exerted in a direction parallel to the line of action of the resistance, or a line joining the centers of the two blocks, in order to obtain the maximum effect. If the rope pulls on the lower block at an angle, the block will be pulled out of the line drawn between the load and the upper block, and the effective pull will be less than the actual pull on the rope in the ratio of the cosine of the angle the pulling rope makes with the vertical, or line of action of the resistance, to unity.

**Differential Pulley.** (Fig. 6.)—Two pulleys, *B* and *C*, of different radii, rotate as one piece about a fixed axis, *A*. An endless chain, *BDECLKH*, passes over both pulleys. The rims of the pulleys are shaped so as to hold the chain and prevent it from slipping. One of the bights or loops *DE*, in which the chain hangs, passes under and supports the running block *F*. The other loop or bight, *HKL*, hangs freely, and is called the hauling part. It is evident that the velocity of the hauling part is equal to that of the pitch-circle of the pulley *B*.

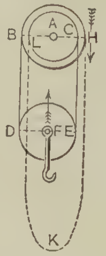

Fig. 6. Differential Pulley

In order that the velocity-ratio may be exactly uniform, the radius of the sheave *F* should be an exact mean between the radii of *B* and *C*.

Consider that the point *B* of the cord *BD* moves through an arc whose length = *AB*, during the same time the point *C* or the cord *CE* will move downward a distance = *AC*. The length of the bight or loop *BDEC* will be shortened by *AB* − *AC*, which will cause the pulley *F* to be raised half of this amount. If *P* = the pulling force on the cord *HK*, and *W* the weight lifted at *F*, then

$$P \times AB = W \times {}^1/_2(AB - AC) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [7]$$

The length of chain required for a differential pulley is: Half the circumference of *A* + half the circumference of *B* + half the circumference of *F* + twice the greatest distance of *F* from *A* + the least length of loop *HKL*. The last quantity is fixed according to convenience.

**A Wheel and Axle, or Windlass,** resembles two pulleys on one axis, having different diameters. If a weight be lifted by means of a rope wound over the axle, the force being applied at the rim of the wheel, the action is like that of a lever of which the shorter arm is equal to the radius of the axle plus half the thickness of the rope, and the longer arm is equal to the radius of the wheel. A wheel and axle is, therefore, sometimes classed as a perpetual lever. If $P$ = the applied force, $D$ = diameter of the wheel, $W$ = the weight lifted, and $d$ = diameter of the axle + the diameter of the rope, $PD = Wd$.

**The Differential Windlass** (Fig. 7) is identical in principle with the differential pulley, the difference in construction being that in the differential windlass the running block hangs in the bight of a rope whose two parts are wound round, and have their ends respectively made fast to, two barrels of different radii, which rotate as one piece about the axis *A*. The differential windlass is little used in practice, because of the great length of rope which it requires.

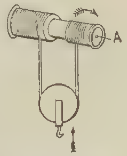

Fig. 7. Differential Windlass

**THE INCLINED PLANE,** as a mechanical element, is supposed to be perfectly hard and smooth, unless friction be considered. It assists in sustaining a heavy body by its reaction. This reaction, however, being normal to the plane, cannot entirely counteract the weight of the body, which acts vertically downward. Some other force, therefore, must be made to act upon the body, in order that it may be sustained.

If, in Fig. 8, the sustaining force *P* acts parallel to the plane, the ratio of the force to the weight *W* is equal to the ratio of the height of the plane to its length, measured on the plane. If the force acts parallel to the base, the ratio of the force to the weight is equal to the ratio of the height to the base.

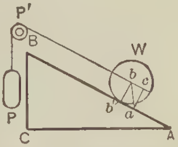

Fig. 8. The Inclined Plane

For forces acting at any other angle, let $\theta$ = angle of plane with the horizon and $\phi$ = angle of direction of applied force with the angle of the plane. Then $P : W :: \sin\theta : \cos\phi$, and

$$P \times \cos\phi = W \times \sin\theta \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [8]$$

If the force acts at any other angle, let $i$ = the angle of the plane with the horizon, and $e$ = the angle of the direction of the applied force with the angle of the plane. $P : W :: \sin i : \cos e$; $P \times \cos e = W \sin i$.

Problems of the inclined plane may be solved by the parallelogram of forces as follows:

Let the weight $W$ be kept at rest on the incline by the force $P$, acting in the line $bP'$, parallel to the plane. Draw the vertical line $ba$ to represent the weight; also $bb'$ perpendicular to the plane, and complete the parallelogram $b'c$. Then the vertical weight $ba$ is the resultant of $bb'$, the measure of support given by the plane to the weight, and $bc$, the force of gravity tending to draw the weight down the plane. The force required to maintain the weight in equilibrium is represented by this force $bc$. Thus the force and the weight are in the ratio of $bc$ to $ba$. Since the triangle of forces $abc$ is similar to the triangle of the incline $ABC$, the latter may be substituted for the former in determining the relative magnitude of the forces, and $P : W :: bc : ab :: BC : AB$.

**The Wedge** is a pair of inclined planes united by their bases. In the application of pressure to the head or butt end of the wedge, to cause it to penetrate a resisting body, the ratio of applied force to the resistance is equal to the ratio of the thickness of the wedge to its length. Let $t$ = thickness and $l$ = length of the wedge, $W$ = resistance, and $P$ = applied force or pressure on the head of the wedge. Then, friction neglected, $P : W :: t:l$, and

$$W = Pl/t \qquad [9]$$

## 2. APPLICATIONS OF THE LEVER

**THE MOVING STRUT** (Fig. 9) is similar to the bent lever, except that one of the arms is missing, and that the force and the resistance to be overcome act at the same end of the single arm. The resistance in the case shown is not the load $W$, but its resistance to being moved, $R$, which may be simply that due to its friction on the horizontal plane, or some other opposing force. When the angle between the strut and the horizontal plane changes, the ratio of the resistance to the applied force changes. When the angle becomes very small, a moderate force will overcome a very great resistance, which tends to become infinite as the angle approaches zero. If $\alpha$ = the angle that the strut makes with the plane on which $W$ rests,

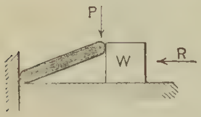

**Fig. 9.** Moving Strut

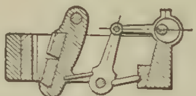

**Fig. 10.** Moving Strut Applied to Stone Crusher

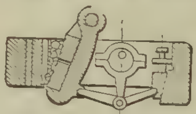

**Fig. 11.** Toggle Joint Applied to Stone Crusher

$$P \times \cos \alpha = R \times \sin \alpha \qquad [10]$$

If $\alpha$ = 5 deg., $\sin \alpha = 0.08716$, $\cos \alpha = 0.99619$ and $R = 11.44\ P$.

The stone crusher, Fig. 10, is a practical example of the use of two moving struts.

**THE TOGGLE-JOINT** is an elbow or knee joint, comprising two links or struts so connected that they may be brought into a straight line when a force is applied at the joint to move them into this position, thus producing great endwise pressure. The toggle-joint is a case of two moving struts placed end to end, the moving force being applied at their junction in a direction at right angles to the direction of the resistance. One end of one strut rests against a fixed abutment and the opposite end of the other strut rests against the body to be moved. In Fig. 12, if $\alpha$ = angle each strut makes with the straight line joining the points about which their outer ends rotate, the ratio of the resistance to the applied force is $R : P :: \cos \alpha : 2 \sin \alpha$, and

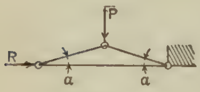

Fig. 12

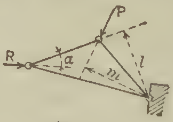

Fig. 13

$$2R \sin \alpha = P \cos \alpha \qquad [11]$$

The ratio varies as the angle varies. becoming infinite when the angle becomes zero.

If the direction of motion of the resisting body is not in the same straight line with the line joining the outer ends of the two struts, and if the applied force does not act at right angles to the line joining the outer ends of the struts, as shown in Fig. 13, the ratio of the applied force to the resistance is

$$P = R \times m \cos \alpha / l \qquad [12]$$

where $\alpha$ is the angle between the direction of motion of the resistance and the center line of the strut immediately adjacent to the resistance, $m$ is the perpendicular distance from the axis of rotation at the abutment to the line of action of the applied force, and $l$ is the perpendicular distance from the axis of rotation at the abutment to the center line of the strut adjacent to the resistance.

The toggle-joint is used where great resistances are to be overcome through very small distances, as in stone-crushers (Fig. 11).

**LINKWORK.**—Two levers, in the form of cranks, connected to two rigid members, one of which supports the crank bearings, constitute a four-bar linkage, generally known as linkwork. In general, any mechanism can be analyzed as a four-bar linkage or a combination of such linkages. Fig. 14 is a diagrammatic representation of a four-bar linkage, in which $A$ and $B$ are the cranks, and $C$ and $D$ the rigid members. Either $C$ or $D$ is fixed. Motion imparted to $A$ or $B$ then will cause definite determinate motion of the other movable members, the character of which depends on the position and length of the various links. The angular speed ratios of the cranks are inversely proportional to the lengths of the perpendiculars from the fixed centers of the cranks to the center line of the connecting-rod ($bn$ and $am$, Fig. 14). Various general combinations of the four-bar linkage are in common use, which are described below.

**Crank and Rocker** (Fig. 15).—In this combination the crank $A$ revolves in a complete circle, imparting an oscillating motion to the rocker arm $B$ through the connecting rod $C$. The link $D$ is fixed by being rigidly attached to the structure of which the linkage is a part. The following relations must hold to permit this linkage to operate:

$$1.\ A + B + C > D; \qquad 2.\ A + D + B > C$$

$$3.\ A + C - B < D; \qquad 4.\ C - A + B > D$$

Angle of oscillation $\alpha$ of the rocker arm $B = \cos^{-1} abd - \cos^{-1} abd$. Either $A$ or $B$ may be the driving crank. If $A$ drives, the mechanism always will operate. If $B$ drives, it will not operate unless a fly-wheel or other aid carries the crank over the dead-center points. An example of the application of this combination is the walking-beam of paddle-wheel steamers.

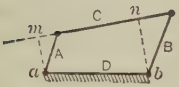

FIG. 14. Four-bar Linkage

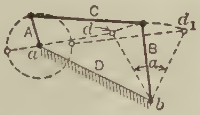

FIG. 15. Crank and Rocker

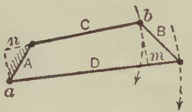

FIG. 16. Drag Link

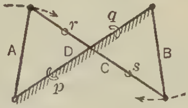

FIG. 17. Non-parallel Equal-crank 4-bar Linkage

**Drag Link** (Fig. 16).—The link $A$ is fixed, $D$ and $C$ are the cranks, and $B$ is the connecting-rod. To permit complete revolution of the cranks the following relations must hold: 1. $B > A + D - C$; 2. $B < D + B - A$. Examples of application are the feathering paddles of paddle-wheel steamers and the drives of slotters.

**Parallel Crank Four-bar Linkage.**—If in Fig. 14 the cranks $A$ and $B$ are of equal length and the connecting-rod $C$ is equal in length to the line of centers of the cranks, link $D$, the two cranks always will turn at the same angular speed. An example of the application of this linkage is the side rod and crank on the driving wheels of locomotives.

**Non-parallel Equal-crank Linkage.**—If the cranks are made of equal length, but pointing in opposite directions from their centers, as in Fig. 17, motion imparted to one crank will cause the other to rotate in the opposite direction. If crank $A$ is given a uniform angular motion, crank $B$ will have a varying angular speed. It is necessary, in order to obtain rotation in opposite directions, to cause the cranks to pass the dead center points in opposite directions by means of some device placed at the instantaneous axis of the connecting-rod when they are at the dead-center position. Such a device may be pins, $r$ and $s$, on the connecting-rod $C$, with open eyes at the corresponding points $p$ and $q$ on the fixed member $D$, with which the pins will mesh. Linkages of this type may be replaced by gears, Fig. 18, which are cut on the circumference of an ellipse whose foci are at $a$, $b$, and $c$, $d$, respectively, and whose major axes are $ad = bc$. The intersection of links $D$ and $C$ at all positions of the linkage is a point on the circumference of the two ellipses, and, therefore, is their point of tangency. An example of the application of such linkwork or elliptical gearing is the slow-advance, quick-return drive of slotters.

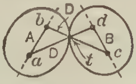

FIG. 18. Elliptical Gearing

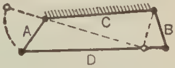

FIG. 19. Slow Motion Linkwork

**Slow Motion Linkwork.**—Fig. 19 shows a four-bar linkage arranged to produce slow motion in the crank $B$. As the crank $A$ is rotated upward it imparts motion to crank $B$, whose angular velocity decreases to zero when the crank $A$ reaches its dead-center position with the connecting-rod $C$ in line with the crank. An example of the application of this linkage is the valve motion of a Corliss engine.

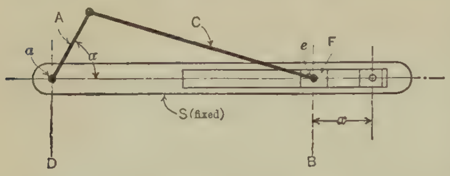

FIG. 20. Linkwork with Sliding Pair

**Linkwork with a Sliding Pair.**—If in Fig. 14, link $D$ be considered as two parallel lines through points $a$ and $b$, perpendicular to $D$ and meeting at infinity, and that on $D$ is mounted a slide in which moves a block attached to the end $e$ of $C$, we have the combination shown in Fig. 20 which is the common form of crosshead and connecting-rod in steam engines. It should be borne in mind that the slide $S$ is not one of the links, but that the slide and the block pivoted to the link $C$ are the equivalent of the infinite links represented by the parallel lines through $a$ and $b$. Two general classes of this combination exist: 1. One member of the sliding pair fixed. 2. One member of the sliding pair turning about a fixed axis. In group 1, the connecting-rod $C$ can be longer, shorter, or equal to the length of the crank $A$. In group 2 the crank can be longer, shorter or equal to the line of centers ($C$, Fig. 22). When one member of the sliding pair is fixed and the connecting-rod is longer than the crank, the movement of the block $F$ from its forward dead-center position is

$$x = A\,(1 - \cos\alpha) + B\{1 - \sqrt{1 - (A^2/B^2)\sin^2\alpha}\} \quad . \quad . \quad . \quad . \quad [13]$$

Another form of this arrangement sometimes used on crank-and-flywheel pumps is shown in Fig. 21. It is known as the Scotch yoke. The slide is at right angles to the center line of the piston rod and the follower block is pivoted to the rotating crank.

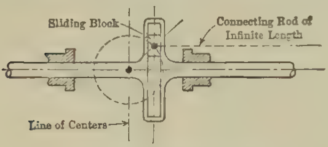

FIG. 21. Scotch Yoke

When the sliding follower is used to drive the crank, means must be provided to carry the crank over the dead-center positions, as by a fly-wheel or by two such linkages, the cranks of which are keyed to the same shaft and set at right angles to each other. An example is the driving cranks of locomotives. Another arrangement is to set the lines of movement of the follower block at an angle of approximately 90 deg. to each other and attach the connecting-rods to the same crank-pin on the crank. Examples of this arrangement are steering engines and some types of hoisting engines.

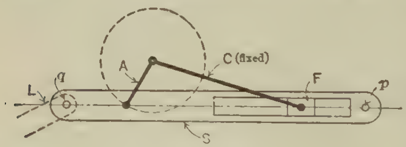

FIG. 22

If the follower $F$ in Fig. 20 is fixed to the frame and can neither turn nor slide, the combination then becomes a case where the line of centers is shorter than the crank. The connecting-rod $C$ then acts as a crank oscillating about the center $e$, the crank $A$ becomes the connecting-rod. If $A$ be given a complete rotation about its axis $a$, the axis will move along the line $ae$ and carry the slide $S$ along with it.

Fig. 22 illustrates a case of the second class noted above wherein the link $C$ is longer than the line of centers $B$. The pin in block $F$ in which link $C$ oscillates is fixed and the follower $F$ rotates around it. As the crank $A$ is rotated the slide $S$ oscillates about the pin, and at the same time slides back and forth over the follower $F$. This mechanism is used in a modified form for a quick-return motion in shapers and other machine tools. The slide $S$ swings on a pin fixed at $P$ and a link $L$, oscillating on the pin $q$, connects the slide $S$ with the head of the machine.

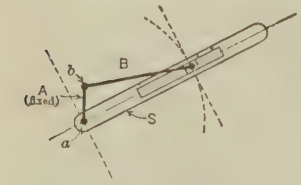

FIG. 23

**Whitworth Quick-return Motion** is a case of Class 2, noted above, where the line of centers is shorter than the crank. In Fig. 23, if the link $A$ is fixed, the link $B$ becomes a crank turning about the center $d$ and causing the slide $S$ to rotate about the axis $a$. The ratio of the angular speeds of the two rotating members varies, since the perpendiculars from them to the center line of the theoretical connecting-rod varies. In the Whitworth quick-return motion, Fig. 24, with the crank $B$ at position 1 the follower $F$ is at the extreme position at one end of the stroke. As the crank is rotated to position 2 through the angle $\alpha$, the follower is carried to its extreme position at the opposite end of the stroke. As the crank further rotates from position 2 to position 1 through the angle $\beta$ the slide is returned to its original position at the other end of the stroke. The ratio of the speed of the forward slow stroke and of the quick return stroke is the ratio $\alpha/\beta$.

For a complete discussion of linkwork, see Schwamb, Merrill and James, Elements of Mechanism (John Wiley & Sons).

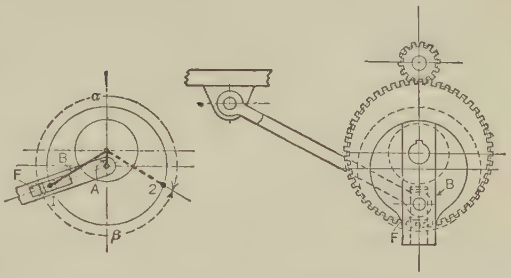

FIG. 24. Whitworth Quick-return Motion

## 3. APPLICATIONS OF THE INCLINED PLANE

**THE SCREW** is an inclined plane wrapped around a cylinder in such a way that the height of the plane is parallel to the axis of the cylinder. If the screw is formed on the internal surface of a hollow cylinder, it is called a nut. When force is applied to raise a weight or overcome a resistance by means of a screw and nut, either the screw or the nut may be fixed, the other being movable. The force generally is applied at the end of a wrench or lever-arm, or at the circumference of a wheel. If $r$ = radius of the wheel or lever-arm, and $p$ = pitch of the screw, or distance between threads, that is, the height of the inclined plane for one revolution of the screw, $P$ = the applied force, and $W$ = the resistance overcome, then, neglecting resistance due to friction,

$$2\pi r \times P = Wp \qquad [14]$$

$$W = 6.283\, Pr \div p \qquad [15]$$

The ratio of $P$ to $W$ is thus independent of the diameter of the screw. In actual screws, much of the power transmitted is lost through friction.

**Efficiency of a Screw.**—Let $\alpha$ = angle of the thread, that is, the angle whose tangent is the pitch of the screw divided by the circumference of a circle whose diameter is the mean of the diameters at the top and bottom of the thread. Then for a square thread

$$\text{Efficiency} = (1 - f \tan \alpha) \div (1 + f \cot \alpha), \qquad [16]$$

in which $f$ is the coefficient of friction. (For demonstration, see Cotterill and Slade, Applied Mechanics.) Since cotan = 1 ÷ tan, we may substitute for cotan $\alpha$ the reciprocal of the tangent, or if $p$ = pitch, and $c$ = mean circumference of the screw,

$$\text{Efficiency} = (1 - fp/c) \div (1 + fc/p) \qquad [17]$$

EXAMPLE.—Efficiency of square-threaded screws $^1/_2$ inch pitch.

| | | | | |
|---|---|---|---|---|
| Diameter at bottom of thread, in. | 1 | 2 | 3 | 4 |
| Diameter at top of thread, in. | $1\,^1/_2$ | $2\,^1/_2$ | $3\,^1/_2$ | $4\,^1/_2$ |
| Mean circumference of thread, in. | 3.927 | 7.069 | 10.21 | 13.35 |
| Cotangent $\alpha = c \div p$ = | 7.854 | 14.14 | 20.42 | 26.70 |
| Tangent $\alpha = p \div c$ = | 0.1273 | 0.0707 | 0.0490 | 0.0375 |
| Efficiency if $f = 0.10$ = | 55.3% | 41.2% | 32.7% | 27.2% |
| Efficiency if $f = 0.15$ = | 45% | 31.7% | 24.4% | 19.9% |

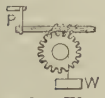

FIG. 25. Worm Gear

The efficiency thus increases with the steepness of the pitch.

The above formulas and examples are for square-threaded screws, and consider the friction of the screw-thread only, and not the friction of the collar or step by which end thrust is resisted, and which further reduces the efficiency. The efficiency is also further reduced by giving an inclination to the side of the thread, as in the V-threaded screw. For discussion of this subject, see paper by Wilfred Lewis, *Jour.* Frank. Inst., 1880; also *Trans.* A.S.M.E., vol. xii, 783, 1891.

**Endless Screw, or Worm-Gear** (Fig. 25) commonly is used to convert motion at high speed into motion at very slow speed. When the handle $P$ describes a complete circumference, the pitch-line of the worm-wheel moves through a distance equal to the pitch of the screw, and the weight $W$ is lifted a distance equal to the pitch of the screw multiplied by the ratio of the diameter of the axle to the diameter of the pitch-circle of the wheel. The ratio of the applied force to the weight lifted, or resistance, is inversely as the velocities, friction not being considered; but the friction in the worm-gear is usually very great, amounting sometimes to 3 or 4 times the useful work done.

If $v$ = the distance through which the force $P$ acts in a given time, say one second, and $V$ = distance the weight $W$ is lifted in the same time, $r$ = radius of the crank or wheel through which $P$ acts, $t$ = pitch of the screw, and also pitch of the teeth on the worm-wheel, $d$ = diameter of the axle, and $D$ = diameter of the pitch-line of the cog-wheel,

$$v = (6.283\,r/t)\,(D/d) \times V \quad [18]$$

$$V = v \times td \div 6.283\,rD \quad [19]$$

$$Pv = WV + \text{friction} \quad [20]$$

**COMPOUND AND DIFFERENTIAL SCREWS.***—**A Compound Screw** consists of a right-hand and a left-hand thread wound on the same or on different cylinders. When wound on the same cylinder (Fig. 27*a*) two nuts are employed. When wound on different cylinders (Fig. 27*b*) one nut is employed. Usually both threads have the same pitch. Each revolution of the screw causes the two nuts to move toward one another a distance equal to the sum of the pitches. Thus two fine threads will give the same relative advance as one coarse thread of double the pitch.

**A Differential Screw** comprises two threads of the same hand, but of different pitches, wound on the same or different cylinders. See Fig. 28*a* and 28*b*. One revolution of the screw causes the nuts, Fig. 28*a*, to move toward each other a distance equal to the difference of the pitches. One revolution of the nut, Fig. 28*b*, causes the screws to approach by the same distance. Thus the use of two coarse threads gives the same relative advance as one fine thread.

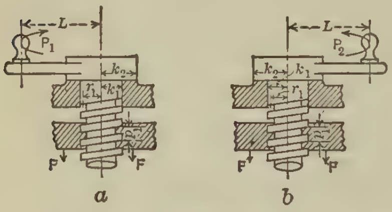

FIG. 26. Simple Screw

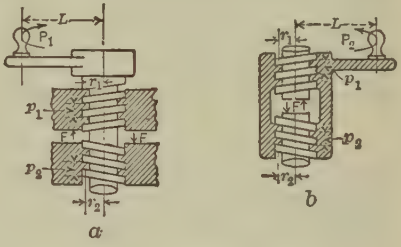

FIG. 27. Compound Screw

**Efficiency.**—The following formulas give the efficiency screws with square threads. In these formulas, $r_1$, $r_2$ = mean radius (to half depth of thread) in.; $c_1$, $c_2$ = mean circumference of screw, in.; $p_1$, $p_2$ = pitch of thread, in.; $p$ = equivalent pitch, in.; $f$ = coefficient of friction; $L$ = length of wrench, in.; $P_1$ = pull on wrench, lb.; $F$ = force transmitted by screw, lb.; $E$ = efficiency. Then

**For Simple Screws**

To raise load (Fig. 26*a*),
$$P_1 = \frac{F}{L}\left\{f\bar{x} + \frac{p_1 + fc_1}{c_1 - fp_1}\,r_1\right\} \quad [21]$$

To lower load (Fig. 26*b*),
$$P_2 = \frac{F}{L}\left\{f\bar{x} + \frac{fc_1 - p_1}{c_1 + fp_1}\,r_1\right\} \quad [22]$$

in which $\bar{x} = {}^2/_3\,\{(k_2^3 - k_1^3)/(k_2^2 - k_1)^2\}$.

If $f = 0$, $\quad P = (F/L)(p_1/6.2832)$, and $E = P/P_1$ [23]

**For Compound Screws** (See Fig. 27),

$$P_1 = \frac{F}{L}\left\{\frac{p_1 + fc_1}{c_1 - fp_1}\,r_1 + \frac{p_2 + fc_2}{c_2 + fp_2}\,r_2\right\} \quad [24]$$

If $f = 0$, $\quad P = (F/L)\{(p_1 + p_2)/6.2832\}$, and $E = P/P_1$ [25]

**For Differential Screws** (See Fig. 28),

$$P_1 = \frac{F}{L}\left\{\frac{p_1 + fc_1}{c_1 - fp_1}\,r_1 + \frac{fc_2 - p_2}{c_2 + fp_2}\,r_2\right\} \quad [26]$$

If $f = 0$, $\quad P = (F/L)\{(p_2 - p_1)/6.2832\}$ and $E = P/P_1$ [27]

For $V$ = threads use $1.15f$ instead of $f$.

---

* Contributed by William H. Boehm.

The load that may be lifted or the force that may be exerted by any of these screws is so much affected by friction that efficiency rarely is as high as 70%. It often is less than 30% for simple screws, and may be less than 5% for differential screws. The coefficient of friction is not uniform, increasing as pitch increases, and being greater with V- than with square threads. Also it varies with the kind of material, the relative smoothness of the contact surfaces and the quality and frequency of lubrication. For screws and nuts of mild steel with square threads, well lubricated, $f$ may be taken as 0.10.

The chief use of the differential screw is to obtain very small movements in precision equipment. Its inefficiency as a means of transmitting power is illustrated by the differential screw punch, below.

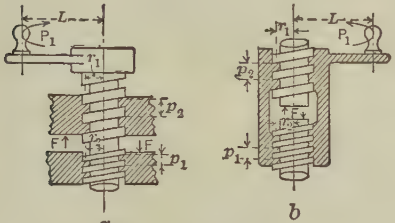

FIG. 28. Differential Screw

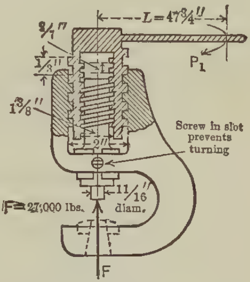

FIG. 29. Differential Screw Punch

**Differential Screw Punch.**—Fig. 29 is a diagram of a differential screw punch in which the pitch of the outer thread is $1/3$ in. and that of the inner thread $2/7$ in., giving an equivalent pitch of $1/21$ in. By jamming the bottom of the outer screw against the top of the inner screw, the device operates as a simple screw punch, with an advance of $1/3$ in. per revolution. The punch was used both as a differential screw punch and a simple screw punch to punch $11/16$ in. holes in $1/4$ in. plate, requiring a force of 27,000 lb. The results with the device used as a differential screw punch were disappointing. The efficiency as computed by formulas [26] and [27], and as actually measured were as follows:

| | Computed | | Actual | |
|---|---|---|---|---|
| | Pull on Lever | Efficiency | Pull on Lever | Efficiency |
| As a differential punch | 92 lb. | 4.6% | 95 lb. | 4.5% |
| As a simple punch | 83 lb. | 36.1% | 82 lb. | 36.7% |

**THE CAM** is a revolving inclined plane. It may be either an inclined plane wrapped around a cylinder in such a manner that the height of the plane is radial to the cylinder, such as the ordinary lifting cam used in stamp mills, Fig. 30, or it may be an inclined plane curved edgewise and rotating in a plane parallel to its base, Fig. 31. The relation of the weight lifted to the applied force is calculated in the same manner as in the case of the screw. See p. 8–09.

**Cam Motions.**—The motion imparted by a cam to its follower usually falls in one of three classes, *viz.*, uniform motion, uniformly accelerated and decelerated motion, and harmonic motion. These three types of motion are illustrated in Fig. 32. In the design of cams the first step is to determine the form of the pitch line, which is done by means of diagrams as illustrated in Fig. 32. Although the diagrams are confined to the three classes of motion noted above, it is obvious that the follower can be caused to conform to any cycle of motion desired. The principles involved in making the diagram for any type of motion are identical with those described below.

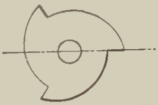

FIG. 30. Lifting Cam

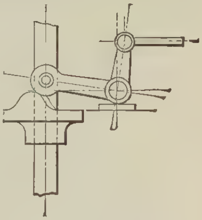

FIG. 31. Edgewise Cam

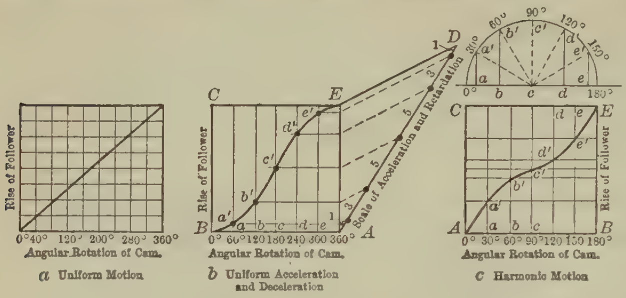
**Uniform-motion Cams**, as the name implies, produce a motion that is uniform from the beginning to the end of the cycle, each rotation of the cam through an equal number of degrees producing an equal increment of rise of the follower. The diagram of a uniform-motion cam is shown in Fig. 32$a$, in which abscissas represent the developed length of angular degrees of rotation, and ordinates represents increments of rise of the follower. Inasmuch as uniform-motion cams cause the follower to start and stop abruptly, they tend to produce shock in the mechanism, and the pitch line of the cam usually is made with a short curve at the beginning and end to gradually accelerate and retard the follower.

**Cams with Uniform Acceleration and Deceleration.**—The method of developing the pitch line is shown in Fig. 32*b*. Line *AB* represents the developed length of the circumference of the cam. Line *BC*, drawn to the same scale as *AB*, represents the total rise of the follower. A rate of acceleration and retardation first must be assumed, the successive steps increasing and decreasing by equal increments, as 1, 3, 5, 5, 3, 1, or 1, 3, 5, 7, 7, 5, 3, 1, etc. Line *AB* is divided into equal parts representing degrees of angular rotation. Line *AD* is drawn at any convenient angle to *AB*, and is divided in proportion to the scale of acceleration and deceleration adopted. A line is drawn from *D* to *E*, and parallels to *DE* are drawn from the points of division on *DA* to intersect *AE*. From these points of intersection abscissas are drawn parallel to *AB* until they intersect the corresponding ordinates at *a′*, *b′*, *c′*, etc., which are points on the pitch line of the cam. The ordinates *aa′*, *bb′*, *cc′*, etc., represents the rise of the follower at the corresponding degrees of angular rotation.



*a* Uniform Motion

*b* Uniform Acceleration and Deceleration

*c* Harmonic Motion

FIG. 32. Cam Motions

**Harmonic Motion Cams** are those in which the rise of the follower is equal to the sine of the angle through which the cam has rotated. The method of determining the pitch line is shown in Fig. 32*c*. As before, *AB* represents the developed length of the circumference of the cam and *AC* the total rise of the follower, both drawn to the same scale. *AB* is divided into equal parts representing equal numbers of degrees of angular rotation. A semi-circle is drawn, of diameter *AC*, and subdivided by the radii *a′c*, *b′c*, etc., to correspond with the angular degrees of rotation into which *AB* has been divided. Perpendiculars to the diameter from the extremities of these radii represent the rise of the follower. These ordinates are transferred to their corresponding position on the diagram as shown and a smooth curve drawn through them, which is the pitch line of the cam.

**Laying Out a Uniform-motion Cam.**—In Fig. 33 a circle of radius *OC*, equal to the smallest radius of the cam is drawn. The vertical radius is prolonged beyond the circle to *B*. The distance 0–6, equal to the maximum movement of the follower, is laid off on *OB* from its intersection with the circle, and divided into any convenient number of equal parts. The semi-circle to the right of *OB* is divided into the same number of equal arcs, and radii are drawn through the points of division. Then with *O* as a center, and with radii equal to *O*-1, *O*-2, *O*-3, etc., arcs are drawn intersecting the corresponding radii at

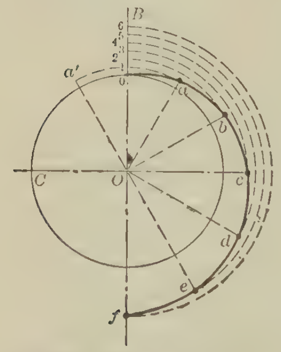


FIG. 33. Uniform-motion Cam

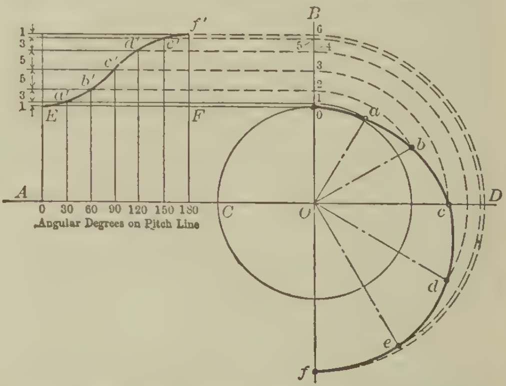

FIG. 34. Cam with Uniform Acceleration and Retardation

*a*, *b*, *c*, etc. The smooth curve drawn through these points is the profile of the cam. The profile of the cam to the left of *OC* is identical, and is drawn in the same manner.

**Laying-out a Cam with Uniform Acceleration and Retardation.**—See Fig. 34. Draw *AD*, and from *O* as a center, with radius *OC*, equal to the smallest radius of the cam, draw a circle. Draw *fOB* perpendicular to *AD*. Draw the tangent *OFE* parallel to *AD*. Divide the semi-circle to the right of *fOB* into any convenient number of equal arcs, and draw radii through the points of division. Lay off on *AC* equal spaces corresponding to the arcs, and erect ordinates at the points of division. Assume a value for the increment or decrement of motion. In the present case it is 2. Hence, with the semi-circle divided into 30-deg. arcs, the relative motion of the follower over the successive arcs will be 1, 3, 5, 5, 3, 1. Note that the motion over the first and last arcs is one-half the value of the assumed increment. Make *f′F* equal to the total movement of the follower. It also is equal to the sum of the increments and decrements of motion, *viz.*, $1 + 3 + 5 + 5 + 3 + 1 = 18$. The length above *EF* of the several ordinates will be

| Angular degrees.................. | 0 | 30 | 60 | 90 | 120 | 150 | 180 |
|---|---|---|---|---|---|---|---|
| Length, fraction of *fF*............ | 0 | $^{1}/_{18}$ | $^{4}/_{18}$ | $^{9}/_{18}$ | $^{14}/_{18}$ | $^{17}/_{18}$ | $^{18}/_{18}$ |

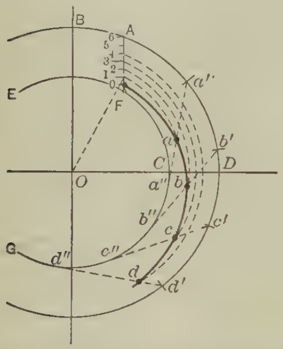

FIG. 35. Cam with Offset Follower

Denote these lengths by points *a′*, *b′*, *c′*, etc., and draw *a′*1, *b′*2, etc. parallel to *EF*, intersecting *OB* at 1, 2, 3, etc. The procedure from this point is the same as for the uniform-motion cam.

**Cam with Offset Follower** (Fig. 35).—Draw the path of the follower *AF* in its position relative to the center *O* of the cam, and divide it according to the character of motion desired. (See Fig. 32.) With *O* as a center and *AO* as a radius describe a circle. Starting at *A*, divide it at *a′*, *b′*, *c′*, etc., to correspond to the positions 1, 2, 3, etc. of the follower. With radius *OC*, equal to the smallest radius of the cam, draw the circle *ECG*. With *O* as a center, with radius equal to *O*1, draw from point 1 on the follower path, the arc 1*a*. From point *a′* draw a tangent *a′a″* to circle *ECG*, intersecting the arc 1*a* at *a*. Similarly draw arcs 2*b*, 3*c*, etc., and tangents *b′b″*, *c′c″*, etc. The intersection of the arcs and tangents at *b*, *c*, etc. are points on the pitch line of the cam.

**Cam with Follower on Rocker Arm** (Fig. 36).—From center *O*, with radius *OC* equal to smallest radius of cam, draw the circle *CG*. Draw the path of the crosshead *JK* in its proper relative position to cam center *O*, and subdivide it according to the type of motion desired. (See Fig. 32.) Locate the center *E* of the rocker arm in its position relative to cam center *O*. Join the point *L*, on the line *AO*, with *E* and prolong *LE* to the opposite end *H* of the rocker arm. With *E* as a center, describe the arcs *HF* and *AL*. Divide arc *HF* to correspond to divisions on the path of the crosshead, by striking arcs from points 0, 1, 2, etc., on *JK* with a radius *JH*. Transfer these points to arc *AL*. With *O* as a center, and *OE* as a radius, draw circle *DEM*, and divide each semi-circle at *a′*, *b′*, *c′*, etc., to correspond with the divisions on *JK*, starting the divisions at *E*, which corresponds to point 0 on *AL*. From *O* as a center, with radii of *O*1, *O*2, *O*3, etc., draw arcs 1*a*, 2*b*, 3*c*, etc. From points *a′*, *b′*, *c′*, etc., with radius equal to *LE*, strike arcs intersecting arcs 1*a*, 2*b*, 3*c*, etc., at *a*, *b*, *c*, etc. The intersections *a*, *b*, *c*, etc., are points on the pitch line of the cam.

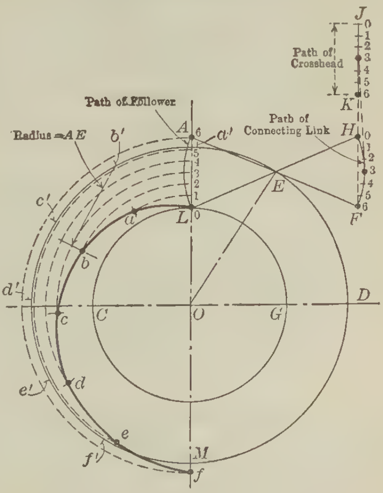

FIG. 36. Cam with Rocker Follower

NOTE.—In the examples of cam layout, Figs. 35 and 36 a uniform-motion cam has been considered. The procedure for any other motion would be identical, except that the points of division of the path of the follower would be determined as illustrated in Fig. 32.

**Correction for Roller Follower.**—A roller follower must be used with cams, unless the force to be transmitted is small. The pitch line of the cam as determined by the above methods then must be corrected. Fig. 37 shows the method of making such corrections. The pitch line as determined above is *ab*. From the center *O* draw radii *Oc*, *Od*, etc. With the points of intersection of the radii with *ab* as centers, draw arcs of radius equal to the radius of the roller follower. The points of intersection of the arcs with the radii are points on the profile of the cam. In Fig. 37 the line *HG* is the profile of a plain cam, and the lines *HG* and *JK* are the boundaries of the slot of a slotted cam.

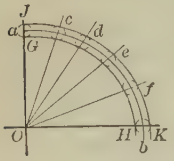

Fig. 37. Profile for Roller Follower

**Cylindrical Cams** comprise a cylinder with a slot cut in the cylindrical surface. The variation in the slope of the slot causes a roller projecting into it to be moved as the cylinder rotates about its axis. Any desired variation in motion can be obtained by appropriate variation of the slot. Fig. 38 shows the method of laying out a cam to give a uniformly accelerated and retarded forward motion, and a uniform return motion in two revolutions of the cam. The line *AB* represents to scale the total movement in one direction of the follower. The line *AA′*, to the same scale, represents the circumference of the cam. The rectangle *AA′B′B* therefore represents the developed surface of the cam. Divide *AB* into the number of equal spaces necessary to represent the desired sequence of acceleration and deceleration increments. Erect ordinates at the division points and locate on them the points of the pitch line. (See Cams with Uniform Acceleration and Retardation, p. 8-13.) Draw the pitch line *AB′* for the forward motion of the follower. The pitch line of the return path is a straight line from *B* to *A′*. Inasmuch as strictly uniform motion would cause shock, the return pitch line is drawn between points slightly short of *B* and *A′*, and joined to *B* and *A′* by arcs. Fig. 39 shows the layout of a cam that gives a harmonic forward motion and a uniform return motion to the follower in a single revolution.

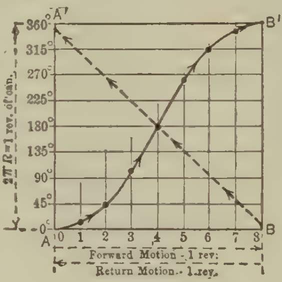

Fig. 38

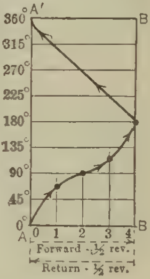

Fig. 39

Cylinder cams also can be designed to give a variety of motions in sequence, during several revolutions. The rectangle representing the developed surface of the cam is divided into half as many parts as the number of revolutions per cycle. The pitch line for that portion of the forward motion of the follower that is to take place during each revolution, then is laid out, by the methods described above, in the portion of the rectangle corresponding to the revolution under consideration. Fig. 40 shows the layout of a cam to give the following cycle of motions in four revolutions: 1. $^3/_4$ revolution, uniform acceleration and deceleration; 2. $^1/_4$ revolution, dwell; 3. $^3/_4$ revolution, uniform acceration and deceleration; 4. $^1/_4$ revolution, dwell; 5. 2 revolutions, return.

**Minimum Radius of Curvature** of the pitch line at any point should not be less than $d + {}^1/_8$ in. where $d$ = diameter of cam roller, in. Otherwise there will be a loss of rise of the follower which will vary in accordance with the sharpness of the angle of intersection of two adjoining curves on the cam.

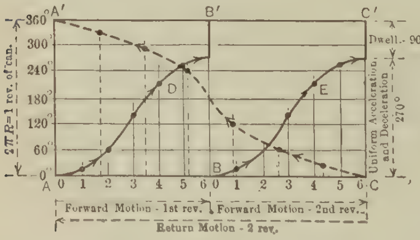

Fig. 40

**Rollers for Cylinder Cams.**—The preferred form of rollers that work in the slot of a cylinder cam is the frustum of a cone, with a corresponding taper of the cross-section of the slot. Straight rollers do not have a true rolling action because of the difference in linear velocity of the top and the bottom of the slot. This sliding of a portion of the roller tends to wear both roller and slot, resulting in eventual backlash and faulty action.

The method of determining the taper of roller and slot is shown in Fig. 41. Draw *AB* equal to the total throw of the cam. Draw *AC* perpendicular to *AB* and of a length equal to the length of pitch line on the surface of the cam through which correct cam action is necessary; for example, lengths *AD* or *BE* in Fig. 40. Lay out *CD* equal to the length of the pitch line at the bottom of the slot. This may be determined by redrawing, for example, Fig. 40, making $AA' = 2\pi r$, where $r$ = diameter of cam cylinder at bottom of slot. At $D$, draw $DE$ parallel to $AB$ and equal in length to $AB$. Then $CB$ equals the developed length of the helix traversed by the top of the roller and $CE$ equals the developed length of the helix traversed by the bottom of the roller. If $CB = a$, $CE = b$, $D$ = diameter of roller at top, and $d$ = diameter of roller at bottom, $d = bD/a$.

The head of the pin on which the roller is mounted should be recessed into the roller at least $^1/_{64}$ in. to avoid sliding contact with the bottom of the slot.

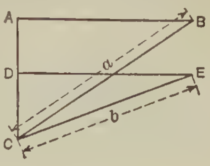

Fig. 41

## 4. THE GYROSCOPE

The Gyroscope is in effect a heavy disc spinning rapidly on its axis, and so mounted that its center is stationary while the axis may take any position whatever. See Fig. 42. A characteristic of the gyroscope, which is utilized in stabilizers to prevent the rolling of ships, in the gyro-compass, in monorail cars, etc., is that when the disc is spinning in a given plane, it resists any attempt to cause it to spin in a different plane. In Fig. 43, the disc of radius $r$ spins about the axis $ZZ$. The disc lies in the plane $QRST$, and the axis $ZZ$ in plane $ABCD$, perpendicular to $QRST$. Now let a force $F$ be applied at one end of the axis $ZZ$, tending to move the disc about its stationary center $O$ into a plane at an angle to $QRST$. The movement of the axis in the direction of $F$ will set up a force $G$, perpendicular to plane $ABCD$ and parallel to plane $QRST$. If this *gyroscopic reaction* $G$ be resisted by some means, as for instance, having the ends of the axis bear against a guide parallel to $ABCD$, the resistance $G'$, equal and opposite to $G$ will tend to impede movement in the direction of $F$. The direction of $G$ is determined by considering $F$ as a pull applied to the end of the axis. Then $G$ will act in the same direction as a point on the disc, in the plane of $F$ and on the same side of the axis, is moving.

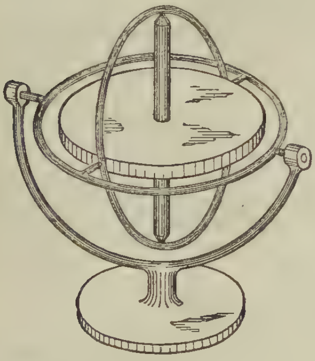

Fig. 42. Gyroscope

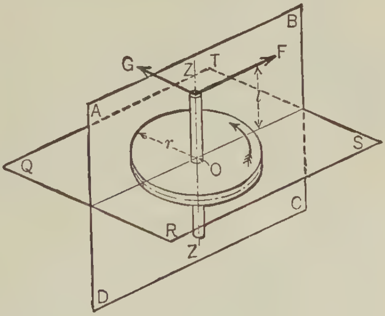

Fig. 43. Forces in the Gyroscope

The magnitude of the forces is as follows. Let $F$ = force applied to move the axis, $m$ = mass of the disc, $= w/g$, $R$ = its radius of gyration, $a$ = acceleration at any instant due to application of force $F$, $l$ = length of lever arm $= OZ$, $N$ = r.p.m. of disc, $v$ = velocity corresponding to acceleration $a$. Then $F = {}^1/_2\, mR^2\, a$, and

$$Gl = mR^2\,(\pi N/30)\,(vl).$$

For a mathematical analysis of the forces in the gyroscope and a discussion of its applications, see Seeley and Ensign, Analytical Mechanics for Engineers, p. 346 (John Wiley & Sons) and Deimel, Mechanics of the Gyroscope (Macmillan).

# MECHANICS

In the design of structures and machines, certain equations and relations, developed by the science of mechanics, frequently must be used. The more commonly used formulas are given below. For a mathematical discussion of these relations, see Eshbach, Handbook of Engineering Fundamentals, Section 4, forming Vol. 1 of this series.

## 1. CENTER OF GRAVITY

The center of gravity of a body or system of bodies rigidly connected is the point about which, if suspended, all parts will be in equilibrium, *i.e.*, without tendency to rotate. In bodies of uniform density, the center of gravity is the center of magnitude.

The center of gravity of **two bodies** is at a point between them, whose distance from their respective centers of gravity is inversely proportional to their weights. The center of gravity of **more than two bodies** is located by determining the center of gravity of two of them; then considering these two as a single body whose weight is concentrated at their common center of gravity, the center of gravity with reference to the third body is located. The process is repeated until all the bodies in the system have been considered.

The center of gravity of regular figures, whether plane or solid, is the same as their geometrical center. The center of gravity of symmetrical figures lies on the axis of symmetry. The center of gravity may be determined by suspending a body or figure from two different points and dropping a plumb line from the point of suspension. The intersection of the plumb lines will be the center of gravity.

The location of the center of gravity of the more common lines, areas and solids is as follows:

**LINES.—Straight Line.**—At middle point of the line.

**Semi-circumference.**—On middle radius $R$, at distance 0.6366 $R$ above diameter.

**Quadrant.**—On middle radius $R$, at distance 0.90028 $R$ from center.

**Circular Arc** of subtended angle $\alpha$, on middle radius $R$, at distance from center of ($R \sin {}^1/_2\,\alpha / {}^1/_2\,\alpha$ in radians).

**Cycloid,** generated by circle of diameter $D$, on perpendicular to middle of base, and ${}^2/_3\,D$ above base.

**PLANE FIGURES.—Triangle.**—At the intersection of two medians $L_1$ and $L_2$, or at a distance of ${}^1/_3\,L$ above the base.

**Parallelogram.**—At intersection of diagonals.

**Trapezium or Trapezoid.**—At the intersection of the two lines joining the centers of gravity of the two triangles formed by drawing first one diagonal and then the other.

**Sector of Circle** of radius $R$, chord $C$, arc $L$; on radius bisecting arc, at ($2\,CR/3\,L$) from center.

**Semi-circle.**—On middle radius, 0.4244 $R$ from center.

**Quadrant.**—On middle radius, 0.600 $R$ from center.

**Segment of Circle** of chord $C$ and area $A$, $C^3/12\,A$ from center.

**Parabolic Surface.**—In the axis, ${}^3/_5$ of its length from vertex.

**Semi-parabola** (surface).—${}^3/_5$ of axis from vertex, and ${}^3/_8$ of semi-base from axis.

**Quadrant of Ellipse** of semi-axes $a$ and $b$. At intersection of parallels to the axes $a$ and $b$, and distant from them, respectively, $\{b - {}^4/_3\,(b/\pi)\}$ and $\{a - {}^4/_3\,(a/\pi)\}$.

**SOLID BODIES.—Prism or Cylinder** (parallel bases).—At middle point of line joining centers of gravity of the bases.

**Oblique Frustum of Right Circular Cylinder** of radius $R$, mean height $H$. In the plane of symmetry at $\{{}^1/_2\,H + (R^2 \tan\alpha / 8\,H)\}$ above base, where $\alpha$ is angle of oblique section to the base, and at (${}^1/_4\,R^2 \tan\alpha / H$) from the axis.

**Cone or Pyramid.**—In the axis, ${}^1/_4$ of its length above the base.

**Paraboloid.**—In the axis, ${}^2/_3$ of its length from the vertex.

**Frustum of Cone or Pyramid.**—In axis, at distance above base of

$$[(a/4) - \{3\,a'^3/4(a^2 + aa' + a'^2)\}],$$

where $a$ = length of line from vertex of complete cone to center of gravity of base, and $a'$ = that portion of it between vertex and top of frustum.

**Hemisphere.**—On radius $R$, perpendicular to base, at ${}^3/_8\,R$ above base.

**Hollow Hemisphere.**—Radii $R$ and $r$. On radius perpendicular to base at

$$\{{}^3/_8\,(R^4 - r^4)/(R^3 - r^3)\} \text{ above base.}$$

**Segment of Sphere.**—Radius $R$; height of segment, $H$. On radius perpendicular to base, at $\{^3/_4\,(2\,R - H)^2/(3\,R - H)\}$.

**Sector of Sphere.**—Radius $R$; height of segment subtended by sector, $H$. On the middle radius, at $^3/_8\,(2\,R - H)$ from center.

**Ellipsoid** of semi-axes, $A$, $B$, and $C$. If an ellipsoid be divided into 8 parts by planes passing through each axis, the center of gravity of each part will lie in the point of intersection of three planes parallel to $A$, $B$, and $C$, and at a distance from them respectively, of $^3/_8\,B$, $^3/_8\,C$ and $^3/_8\,A$. See Fig. 1.

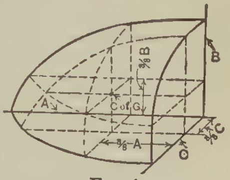

FIG. 1

## 2. MOMENT OF INERTIA

**THE MOMENT OF INERTIA OF A BODY** with respect to an axis is the algebraic sum of the products of the weight of each elementary particle multiplied by the square of its distance from the axis. If $w_1, w_2 \ldots w_n$ represent the weights of the several particles, and $r_1, r_2 \ldots r_n$, their respective distances from axis $XX$, then the moment of inertia with respect to the axis $XX$ is $I = w_1 r_1^2 + w_2 r_2^2 + \ldots w_n r_n^2$. $I$ is least when the axis passes through the center of gravity of the body.

Moment of inertia as applied to areas, as the cross-section of structural beams, equals $ar^2$, where $a$ is any elementary area. Moments of inertia of the more commonly used bodies, about different axes, are given in Table 1. Moments of inertia of structural shapes are given on pp. 17–50 to 17–72.

**Moment of Inertia about Parallel Axes.**—If the moment of inertia $I$ of an area or solid, about an axis through the center of gravity, is known, its moment of inertia $I'$ about any parallel axis may be found by the formula $I' = I + (d^2 \times A)$, where $d$ = distance between the two axes and $A$ = the area or weight.

**Polar Moment of Inertia.**—If the moments of inertia of an area with respect to two rectangular axes in the same plane are known, its moment of inertia about an axis perpendicular to this plane, and passing through the intersection of the axes is equal to the sum of the moments of inertia about the two rectangular axes. This latter is known as the polar moment of inertia, and is designated by $J$. If $I$ and $I'$ are the moments of inertia about the rectangular axes $XX$ and $YY$, $J = I + I'$.

**Moment of Inertia about Any Axis.**—If $b$ = breadth and $h$ = depth of a rectangular section, its moment of inertia about its central axis (parallel to the breadth) is $^1/_{12}\,b\,h^3$; and about one side is $^1/_3\,b\,h^3$. If a parallel axis exterior to the section is taken, and $d$ = distance of this axis from the farthest side and $d_1$ = its distance from the nearest side, $(d - d_1) = h$, the moment of inertia about this axis is $^1/_3\,b\,(d^3 - d_1^3)$.

### Table 1.—Moment of Inertia of Commonly Used Bodies

$W$ = weight of body; $w$ = weight of elementary unit of body; $d$ = distance of center of gravity of body from axis.

| | | | |
|---|---|---|---|
|  | Solid rod, axis perpendicular to axis of rod,<br>$I = W\left\{(l^2/3) + d^2\right\}$ |  | Solid cylinder, axis coincident with axis of cylinder,<br>$I = WD^2/8$ |
|  | Hollow cylinder about its axis,<br>$I = {}^1/_8\,W(D_1^2 + D_2^2)$.<br>Thin hollow cylinder,<br>$I = {}^1/_4\,WD_1^2$ |  | Solid cylinder, axis perpendicular to axis of cylinder,<br>$I = W\left\{\frac{D^2}{16} + \frac{l^2}{12} + d\right\}$ |
|  | Thin circular plate, axis in its own plane,<br>$I = W\left\{(r^2/4) + d^2\right\}$ |  | Thin circular plate, axis perpendicular to plate,<br>$I = W\left\{(r^2/2) + d^2\right\}$ |
|  | Circular ring, axis perpendicular to plane,<br>$I = W\left\{{}^1/_2(R^2 + r^2) + d^2\right\}$ |  | Circular ring about axis XX,<br>$I = w\,\pi R m^2(R^2 + {}^5/_4 m^2)$.<br>About axis YY,<br>$I = {}^1/_2\,w\,\pi^2 R^2 m^2(4R^2 + 3m^2)$ |
|  | Solid sphere about diameter,<br>$I = {}^2/_5\,Wr^2$ |  | Hollow sphere about diameter,<br>$I = {}^8/_{15}\left\{w\,\pi(R^5 - r^5)\right\}$<br>Thin sphere, $I = {}^2/_3\,WR^2$ |
|  | Rectangular prism, axis through c. of g. perpendicular to face $mn$,<br>$I = {}^1/_{12}\,W(m^2 + n^2)$ |  | Right circular cone, axis XX,<br>$I = {}^3/_5\,W({}^1/_4\,r^2 + h^2)$<br>About its axis of revolution,<br>$I = {}^3/_{10}\,W\,r^2$ |

**Moment of Inertia of Compound Shapes.**—The moment of inertia of a compound shape about any axis equals the sum of the moments of inertia with reference to the same axis of all the rectangular portions composing it. It also equals the moment of inertia about a parallel axis through its center of gravity + (area of section × square of distance between axes). From this, the moments of inertia or radii of gyration of any single section being known, values may be found for any combination of these sections.

## 3. CENTER AND RADIUS OF GYRATION

**THE CENTER OF GYRATION** with reference to an axis is that point at which the entire weight of a body may be concentrated without changing its moment of inertia. In a revolving body, it is the point at which the whole weight of the body may be conceived to be concentrated.

**RADIUS OF GYRATION** is the distance from the axis to the center of gyration. Let $W$ = weight of the body; $I$ = its moment of inertia; $k$ = its radius of gyration. Then $I = W k^2 = \Sigma w\, r^2$; $k = \sqrt{I/W} = \sqrt{\Sigma w\, r^2 / W}$. The radius of gyration is least when the axis passes through the center of gravity, and is then known as the principal radius of gyration. Let $k$ = principal radius of gyration; $k'$ = any other radius of gyration; $d$ = distance between the axes of $k$ and $k'$. Then $k' = \sqrt{k^2 + d^2}$. Table 2 gives principal radii of gyration of the more common areas and solids, except structural shapes, for which see pp. 17–50 to 17–72.

## 4. VELOCITY AND ACCELERATION

**VELOCITY** is the rate of motion, or speed of a body at any instant. If $s$ = space, ft., passed over in $t$ sec., and $v$ = velocity, ft. per sec., when $v$ is uniform, $s = vt$; $v = s/t$. If $v$ varies uniformly, the mean velocity $v_m = 1/2\,(v_1 + v_2)$, where $v_1$ and $v_2$ are the velocities at beginning and end of time $t$, respectively. $s = 1/2\,(v_1 + v_2)t$.

**Table 2.—Principal Radii of Gyration and Squares of Radii of Gyration**

(For radii of gyration of sections of columns, see pp. 17–50 and 17–77)

| Surface or Solid | Radius of Gyration | Square of Radius of Gyration |
|---|---|---|
| Parallelogram: height $h$, axis at its base | $0.5773\,h$ | $1/3\,h^2$ |
| Parallelogram: height $h$, " mid-height | $0.2886\,h$ | $1/12\,h^2$ |
| Straight rod: length $l$, or thin rectangular plate, axis at end | $0.5773\,l$ | $1/3\,l^2$ |
| Straight rod: length $l$, or thin rectangular plate, " mid-length | $0.2886\,l$ | $1/12\,l^2$ |
| Rectangular prism: axes $2a$, $2b$, $2c$, referred to axis $2a$ | $0.577\sqrt{b^2 + c^2}$ | $(b^2 + c^2) \div 3$ |
| Parallelopiped: length $l$, base $b$, axis at one end, at mid-breadth | $0.289\sqrt{4l^2 + b^2}$ | $\dfrac{4l^2 + b^2}{12}$ |
| Hollow square tube: | | |
| outer side $h$, inner $h'$, axis mid-length | $0.289\sqrt{h^2 + h'^2}$ | $(h^2 + h'^2 \div 12$ |
| very thin, side $= h$, axis mid-length | $0.408\,h$ | $h^2 \div 6$ |
| Thin rectangular tube: sides $b$, $h$, axis mid-length | $0.289\sqrt{\dfrac{h + 3b}{h + b}}$ | $\dfrac{h^2}{12} \cdot \dfrac{h + 3b}{h + b}$ |
| Thin circular plate: radius $r$, diameter $h$, axis on diameter | $1/2\,r$ | $1/4\,r^2 = h^2 \div 16$ |
| Flat circular ring: diameters $h$, $h'$, axis on diameter | $1/4\sqrt{h^2 + h'^2}$ | $(h^2 + h'^2) \div 16$ |
| Solid circular cylinder: length $l$, axis on diameter at mid-length | $0.289\sqrt{l^2 + 3r^2}$ | $\dfrac{l^2}{12} + \dfrac{r^2}{4}$ |
| Circular plate: solid wheel of uniform thickness, or cylinder of any length, referred to axis of cylinder | $0.7071\,r$ | $1/2\,r^2$ |
| Hollow circular cylinder, or flat ring: $l$, length; $R$, $r$, outer and inner radii. Axis: 1, longitudinal axis; 2, diameter at mid-length | $0.7071\sqrt{R^2 + r^2}$ | $(R^2 + r^2) \div 2$ |
| | $0.289\sqrt{l^2 + 3(R^2 + r^2)}$ | $\dfrac{l^2}{12} + \dfrac{R^2 + r^2}{4}$ |
| Same: very thin, axis its diameter | $0.289\sqrt{l^2 + 6R^2}$ | $\dfrac{l^2}{12} + \dfrac{R^2}{2}$ |
| " radius $r$; axis, longitudinal axis | $r$ | $r^2$ |
| Circumference of circle, axis its center | $r$ | $r^2$ |
| " " " " " diameter | $0.7071\,r$ | $1/2\,r^2$ |
| Sphere: radius $r$, axis its diameter | $0.6325\,r$ | $2/5\,r^2$ |

If the velocity varies, but not uniformly, $v$ for a very short interval of time $= s/t$, or in the calculus, $v = ds/dt$.

**ACCELERATION,** $a$, is the change in velocity occurring in unit time. The unit of $a$ is 1 ft. per sec. per sec. For uniformly accelerated motion, $a$ is constant.

$a = (v_2 - v_1)/t$; $v_2 = (v_1 + at)$; $v_1 = (v_2 - at)$; $t = (v_2 - v_1)/a$.

If the body starts from rest, $v_1 = 0$, and the mean velocity $v_m = v_2/2$; $v_2 = 2v_m$; $a = v_2/t$; $v_2 = at$; $v_2 - at = 0$; $t = v/a$.

For acceleration due to gravity, and of falling bodies, see p. 8–21.

**Deceleration or Retarded Motion.** — If a body starts with a velocity $v_1$ and comes to rest, $v_2 = 0$, and $s = {}^1/_2\, v_1 t$. In any case, if the change in velocity is $v$, $s = {}^1/_2\, vt = v^2/2a = {}^1/_2\, at^2$.

For a body starting from or ending at rest, $v = at$; $s = {}^1/_2\, vt = {}^1/_2\, at^2$; $v^2 = 2as$.

**CURVES OF VELOCITY AND ACCELERATION.**—If the velocity or acceleration are not uniform, or are represented by complex equations, they may be studied by plotting space, velocity or acceleration against time. In Fig. 2, the space passed over is plotted as ordinates with seconds of time as abscissas. The angle made by the tangent to the curve at any point determines the velocity at that instant. Thus, the tangent $BC$ at point $A$ intersects the axis of abscissas at $C$ and the velocity at $A$ is $(AD/CD) = {}^3/_2$ ft. per sec. Since the slope of the tangent is upward, the velocity is increasing, *i.e.*, the point under consideration is being accelerated. The slope of tangent at $F$ is downward, and hence the motion of the point is being retarded. If the curve at any point is parallel to the axis of abscissas, the motion is uniform.

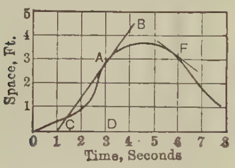

Fig. 2

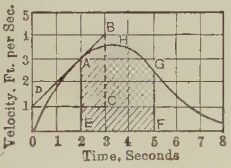

Fig. 3

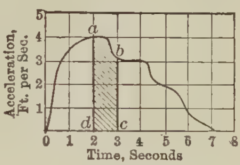

Fig. 4

In Fig. 3, velocity is plotted as ordinates and time as abscissas. The angle of the tangent to the curve at any point will represent the acceleration at that instant. The acceleration at $A$ is $(BC/CD) = {}^3/_3 = 1$ ft. per sec. per second. As before, an upward slope represents acceleration, while a downward slope would represent retardation or deceleration. The area under the curve between any two ordinates will represent the space passed over in that interval of time. Thus area $AEFGH \div EF = 10 \div 3 = 3\,{}^1/_3$ ft.

In Fig. 4, acceleration is plotted as ordinates and time as abscissas. The angle of the tangent to the curve at any point will represent the velocity at that instant and the area under the curve between two ordinates $ad$ and $bc$ will represent the change in velocity during the interval.

For *uniform motion* the space-time curve is a straight line, inclined to the axis of abscissas, and the velocity-time curve is a straight line parallel to the axis of abscissas.

For *constant acceleration* or *constant retardation* the space-time curve is a parabola, and the velocity-time curve is a straight line, inclined away from or toward the axis of abscissas, depending upon whether the velocity increases or decreases. The acceleration-time curve is a straight line, parallel to the axis of abscissas.

**ANGULAR VELOCITY OF A TURNING BODY.**—Let $r$ = radius of a turning body, ft.; $n$ = rev. per min.; $v$ = linear velocity of a point on the circumference, ft. per sec., and $60\,v$ = velocity in ft. per min. Then $v = 2\pi rn/60$; $60\,v = 2\pi rn$.

**ANGULAR VELOCITY** denotes the angle through which any radius of a body turns in 1 sec., or the rate at which any point in it, of unit radius, is moving in ft. per sec. The unit of angular velocity is the *Radian* $= 180/\pi$ deg. $= 57.3$ deg. If $A$ = angular velocity, $v = Ar$; $A = v/r = 2\pi rn/60$. The linear velocity of a point in a rotating body is proportional to its distance from the axis.

**ANGULAR ACCELERATION** is the rate at which angular velocity varies with respect to time.

## 5. FORCE, WORK AND ENERGY

**UNIFORMLY ACCELERATED MOTION.**—Let $f$ be a constant force, acting for $t$ sec. on a body, at rest at the beginning of the time, but free to move without friction, the weight of the body being $w$ lb. The body will move at a gradually increasing velocity $v$, which varies as $ft/w$.

If $v$ is in ft. per sec., $f$ in standard pounds of force,* $t$ in seconds, and $w$ in pounds, the equations that govern the motion of the body are as follows:

Let $K$ = a constant derived by experiment. Then $v = Kft/w$. The value of $K$ at sea level at latitude 45 deg. is 32.1740, and is twice the distance that a body *in vacuo* would fall in 1 sec. It usually is designated as $g$.† The fundamental equation then is

$$v = ftg/w. \qquad [1]$$

Let $S$ = distance through which the body moves. If $v$ varies directly as time (uniformly accelerated motion), then $S = v_m t$, where $v_m$ = mean velocity during time $t$. If $v_0$ = initial velocity, and $v$ = final velocity at end of time $t$, $v_m = (v_0 + v)/2$. For a body starting from rest $v_0 = 0$, and $v_m = v/2$. Hence, $S = {}^1/_2\, vt$; $v = 2\,S/t$; $t = 2S/v$. Substituting $v = 2S/t$ in equation [1],

$$S = ft^2\, g/2\,w. \qquad [2]$$

If $f = w$, which is true of a falling body at latitude 45 deg. at sea level, equation [1] becomes $v = gt$. Substitute in this equation $t = S/v$; then

$$v = 2\,gS/v, \quad \text{and} \quad v = \sqrt{2\,gS}. \qquad [3]$$

In equation [2], put $f = w$. Then $S = {}^1/_2\, gt^2$.

From 1, by transposition,

$$ft = w \times v/g = v \times w/g. \qquad [4]$$

$w/g$, the mass of the body frequently is designated as $m$, whence [4] becomes

$$ft = mv. \qquad [5]$$

Substitute in [4], $t = 2S/v$. Then $f\,2\,S/v = v \times w/g$, whence,

$$fS = {}^1/_2\, mv^2 \qquad [6]$$

By definition acceleration $a = v/t$, whence from [5],

$$f = ma‡. \qquad [7]$$

If two forces $f$, $f_1$, act on a body at different times, producing accelerations $a$, $a_1$, then $\dfrac{f = ma}{f_1 = ma_1}$, whence

$$f/f_1 = a/a_1. \qquad [8]$$

These eight equations and their transformations will solve all problems of uniformly accelerated motion.

**FORCE OF ACCELERATION.**—To produce an acceleration of $g$ (*i.e.*, 32.174 ft. per sec. per sec.), force required, $f = mg = (w/g)g = w$, or the weight of the body. Since $f = ma$, $f = m(v_2 - v_1)/t$, where $v_2$ and $v_1$ = respectively, initial and final velocities at beginning and end of time $t$. Also $f = mg = (w/g)/\{(v_2 - v_1)/t\} = (w/g)a$; $f/w = a/g$. In problems where the local attraction of gravity is a factor, the local value of $g$ must be used if accuracy is necessary.

Example.—Required the tension in a cord lifting 100 lb. vertically through 80 ft., at velocity uniformly increasing from 0 to 40 at the end of 4 sec. Local value of $g$ = 0.998 × standard value = 32.108; $v_m = 20$; final velocity $v_2 = 2v_m = 40$. Acceleration $a = v_2/4 = 10$. Force required to produce acceleration $= f_a = ma = wa/g = (100 \times 10)/32.174 = 31.08$ lb. The standard value of $g$ (32.174) is used here, since force required for acceleration is independent of gravity. Force required to lift the weight without acceleration $= f_w = 100 \times 0.998 = 99.8$ lb. The factor 0.998 is used in this equation because the force of gravity in the given locality is less than standard. Total tension in cord $= f_a + f_w = 130.88$ lb.

**Resistance to Acceleration** equals the force necessary to produce acceleration $= (w/g)\{(v_2 - v_1)/t\}$.

**FORMULAS FOR ACCELERATED MOTION.**—For cases of uniformly accelerated motion, other than those of falling bodies, we have the formulas already given, $f = (w/g)a$;

---

* The pound avoirdupois is the unit of force used by American and British engineers. It is the force with which gravity attracts 1 lb. of matter at sea level at 45 deg. latitude, and which would give to 1 lb. of matter an acceleration of 32.1740 ft. per sec.

In the centimeter-gram-second system, the unit of force is the *dyne*. It is that force which acting on a mass of 1 gram will produce in 1 second a velocity of 1 centimeter per second. A dyne = 1/980.665 gram.

The absolute unit of force, used in physical laboratories, is the *Poundal*. It is that force which acting for 1 second on a mass whose weight is 1 lb. at London will produce a velocity of 1 ft. per second.

† $g$, commonly called acceleration due to gravity, may be considered as: an abstract figure, the constant in equation [1]; the velocity acquired at the end of 1 sec. by a freely falling body; the distance that a body would travel in 1 sec. at its then velocity if the force ceased to act and velocity remained constant.

‡ Equation [7] sometimes is read "force equals mass times acceleration," which is strictly true in the dyne-centimeter-gram-second, or "absolute" system of measurements, in which force is measured in dynes, but it is not true in the pound-foot-second system, nor in the metric system where the kilogram is used as a unit of both force and quantity of matter, unless it is understood that the word "mass" means the quotient of $W$ divided by $g$.

$f = (w/g)\{(v_2 - v_1)/t\}$. If the body starts from rest, $v_1 = 0$, $v_2 = v$, and $f = (w/g)(v/t)$; $f g t = w v$. We also have $S = {}^1/_2\, v t$. Transforming and substituting 32.174 for $g$,

$$f = w v^2/64.35\, S = w v/32.17\, t = w S/16.09\, t^2. \quad . \quad . \quad . \quad . \quad . \qquad [9]$$

$$w = 32.17\, f t/v = 64.35\, f S/v^2. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad [10]$$

$$S = w v^2/64.35\, f = 16.09\, f t^2/w = v t/2. \quad . \quad . \quad . \quad . \quad . \qquad [11]$$

$$v = 8.02\sqrt{f S/w} = 32.17\, f t/w. \quad . \quad . \quad . \quad . \quad . \quad . \qquad [12]$$

$$t = w v/32.17\, f = (1/4.01)\sqrt{w S/f}. \quad . \quad . \quad . \quad . \quad . \qquad [13]$$

For varying velocity, $f = w\{(v_2^2 - v_1^2)/64.35\, S\}$. . . . . . . . . . . . . . . . [14]

**WORK OF ACCELERATION.**—The work $P$ done in accelerating a body is $f \times S$, where $f$ = force producing acceleration and $S$ = distance covered in time $t$. The force, $f = m a = (w/g)\{(v_2 - v_1)/t\}$, and

$$P = (w/g)\{(v_2 - v_1)/t\}S \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad [15]$$

EXAMPLE.—Work required to move horizontally 80 ft. in 4 sec. a frictionless body weighing 100 lb., at uniformly increasing velocity. Mean velocity, $v_m = 20$; initial velocity $v_1 = 0$; final velocity $v_2 = 2\, v_m = 40$; $a = (v_2 - v_1)t = 40/4 = 10$; $f = (w/g)a = (100/32.16) \times 10 = 31.1$ lb.; $S = 80$; $P = f S = 31.1 \times 80 = 2488$ ft.-lb. Energy stored in the body at the final velocity $v = 40$, equals the work of acceleration.

$E = {}^1/_2\, m v^2 = {}^1/_2\, (w/g)v^2 = (100 \times 40^2)/(2 \times 32.16) = 2488$ ft. lb.

**WORK OF ACCELERATED ROTATION.**—Let $A$ = angular velocity, radians, of a particle of weight $w$, rotating at unit radius $r$ around an axis. The velocity $v_1 = A_1 r$. If angular velocity is accelerated to $A_2$, velocity of particle becomes $v_2$. Increase in velocity is $(v_2 - v_1) = r(A_2 - A_1)$, and the work of acceleration is

$$P_a(w/g)\{(v_2^2 - v_1^2)/2\} = (w r^2/g)\}(A_2^2 - A_1^2)/2\}. \quad . \quad . \quad . \quad . \quad . \qquad [16]$$

The work of a rotating body around an axis is

$$\Sigma(w/g) \times {}^1/_2\, (v_2^2 - v_1^2) = (A_2^2 - A_1^2)/2g \times \Sigma w r^2, \quad . \quad . \quad . \quad . \quad . \qquad [17]$$

where $\Sigma w r^2$ = moment of inertia of the body.

**MEASURE OF ENERGY** in a body is the product of its weight and the height from which it must fall to acquire actual velocity. If $v$ = velocity, ft. per sec., $h$ = height, ft., corresponding to velocity $= v^2/2g$ (see Falling Bodies below), and if $w$ = weight, lb., energy, $E = {}^1/_2\, m v^2 = w v^2/2g = w h$. Since energy is the capacity for doing work, the units of work and energy are equivalent, or $FS = {}^1/_2\, m v^2 = w h$.

In a rotating body, $E = A^2 I/2g$, where $A$ = angular velocity, radians, and $I$ = moment of inertia. Also, $E = w v^2/2g$, where $v$ = velocity of center of gyration.

**THE LAW OF GRAVITATION** states that two bodies attract each other with a force directly proportional to their masses and inversely proportional to the square of the distance between them. Let $F$ = force with which two bodies of masses $m_1$ and $m_2$ attract each other, and $d$ = distance between them. Then $F = C m_1 m_2/d^2 = C(w_1/g)(w_2/g)/d^2 = C w_1 w_2/d^2 g^2$ where $C$ = gravitation constant of two spheres of unit mass, *i.e.*, the force with which they attract each other through unit distance. $C = 3.31 \times 10^{-11}$ if $F$, $w$ and $d$ are in pounds and feet.

**MOMENTUM. IMPULSE.**—Momentum is the product of the mass and velocity of a body, *i.e.*, momentum $= m v = (w/g)v$. In equation [5], $f t = m v$, the expression $f t$ is sometimes termed the impulse, whence Impulse = Momentum.

**FALLING BODIES.**—The formulas for falling bodies are derived from the equations [9] to [14] by putting $f = w$. If $g$ be taken as 32.16 (value at 40 deg. latitude), $v$ = velocity, ft. per sec. at end of time $t$; $h$ = height of fall, ft., then

$$v = g t = 32.16\, t = \sqrt{2\, g h} = 8.02\sqrt{h} = 2h/t. \quad . \quad . \quad . \quad . \quad . \quad . \qquad [18]$$

$$h = g t^2/2 = 16.08\, t^2 = v^2/2g = v^2/64.32 = v t/2. \quad . \quad . \quad . \quad . \quad . \qquad [19]$$

$$t = v/g = v/32.16 = \sqrt{2h/g} = \sqrt{h}/4.01 = 2h/v. \quad . \quad . \quad . \quad . \quad . \qquad [20]$$

$u$ = space fallen through during $T$th sec.

$$= h_t - h_{t-1} = (g t^2/2) - g(t - 1)^2/2 = (g/2)(2t - 1) = g(t - 1)/2. \qquad [21]$$

Solving the above equations, the values of $v$, $h$, $t$, $u$, are as follows:

| $t =$ | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
|---|---|---|---|---|---|---|---|---|---|---|
| $g = 32.16 \times$ | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 |
| $v = 32.16 \times$ | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
| $u = (32.16/2) \times$ | 1 | 3 | 5 | 7 | 9 | 11 | 13 | 15 | 17 | 19 |
| $h = (32.16/2) \times$ | 1 | 4 | 9 | 16 | 25 | 36 | 49 | 64 | 81 | 100 |

**Value of $g$** increases with latitude and decreases with elevation above sea-level. At Philadelphia, latitude 40 deg., $g = 32.16$. Everett's formula for $g$ is

$$g = 32.173 - 0.082 \cos 2 \text{ lat. } 45 \text{ deg.} - 0.000003 \text{ height in ft.} \quad . \quad . \quad . \qquad [22]$$

The standard value of $g$ at latitude 45 deg. given by International Conference on Weights and Measures, Paris, 1901, is 32.1740. The value of $\sqrt{2g}$ decreases about 0.0004 per 1000 ft. elevation above sea-level. For all ordinary calculations in the U. S., $g = 32.16$, and $\sqrt{2g} = 8.02$. In England, $g = 32.2$; $\sqrt{2g} = 8.025$. C. S. Pierce gives limiting values in the U. S. as: At latitude 49 deg., at sea-level, $g = 32.186$; at latitude 25 deg., 10,000 ft. above sea-level, $g = 32.089$.

Local values of $g$ are used in calculations involving local gravitational force, as falling bodies, lifting weights, and water powers. In all cases involving the expression $w/g$, the standard value, $g = 32.1740$ should be used.

**CENTRIFUGAL FORCE.**—A body revolving in a curved path of radius $= R$ ft. exerts a force, called centrifugal force, on the arm or cord that restrains it from moving in a straight line. If $W$ = weight of body, lb., $N$ = rev. per min., $v$ = linear velocity of center of gravity of body, ft. per sec., $g = 32.174$,

$$v = \frac{2\,\pi RN}{60}. \qquad [23]$$

$$F = \frac{Wv^2}{gR} = \frac{Wv^2}{32.174\,R} = \frac{W4\,\pi^2\,RN^2}{3600\,g} = \frac{WRN^2}{2933.9} = 0.00034084\,WRN^2 \text{ lb.} \qquad [24]$$

If $n$ = rev. per sec., $F = 1.2270\,W\,r\,n^2$.

The force that restrains the body from moving in a straight line, *i.e.*, the tension in the cord or arm, is called *centripetal force*, and is equal and opposite to the centrifugal force.

## 6. OSCILLATION AND PERCUSSION

**CENTER OF OSCILLATION.**—A body oscillates about a fixed axis, outside of its center of gravity. The center of oscillation is a point on the line drawn from the center of gravity of the body, perpendicular to the axis, whose motion is the same as it would be were the entire mass of the body there concentrated and allowed to vibrate as a pendulum.

**RADIUS OF OSCILLATION** is distance from center of oscillation to point of suspension $= r = R^2/l$; $R$ = radius of gyration, $l$ = distance from point of suspension to center of gravity. Centers of suspension and oscillation are mutually convertible. The center of oscillation of a straight line, or uniform thin bar or cylinder of length $L$ suspended from and oscillating about one end, is $^2/_3\,L$ from the axis. If the point of suspension is $^1/_3\,L$, the center of oscillation is again $^2/_3\,L$ from the axis, *i.e.*, at end of bar. The time of oscillation $t$ is the same in both cases. If point of suspension is at center of gravity, in the simple equivalent pendulum $L = \infty$ and $t = \infty$.

A sphere of radius $R$ is suspended by a cord. Let $h$ = distance of axis of motion to center of sphere, $h'$ = distance of center of oscillation to center of sphere, $r$ = radius of oscillation $= h + h' = h + {}^2/_5\,(R^2/h)$. If the sphere oscillates about an axis tangent to the surface $h = R$ and $r = R + {}^2/_5\,R$.

**Table 3.—Length of Radius of Oscillation of Plane Figures**

| Figure | Direction of Vibrations | |
|---|---|---|
| | Perpendicular to Plane of Figure | In Plane of Figure |
| Isosceles triangle | $^3/_4$ altitude | |
| Circle | $^5/_8$ diameter | $^3/_4$ height |
| Parabola | $^5/_7$ height | $^5/_7$ height + $^1/_3$ parameter *<br>$^4/_7$ height + $^1/_2$ parameter † |
| Rectangle | | $^2/_3$ diagonal ‡ |

* Suspended by vertex. † Suspended by middle of base. ‡ Suspended by one angle.

**THE PENDULUM.**—The *Simple Pendulum* is an ideal body concentrated at the center of oscillation, suspended from a fixed point by a weightless string. A *Compound Pendulum* is a body of any form suspended from a fixed axis about which it oscillates by force of gravity. The equivalent simple pendulum has the same weight and the same moment of inertia referred to an axis through point of suspension, and it vibrates in the same time. The ordinary pendulum of given length vibrates in equal times when the angle of vibration does not exceed 2 deg. or 2 $^1/_2$ deg. on each side of the vertical. This property is *isochronism*.

Let $T$ = time of vibration, sec., $l$ = length of simple pendulum, $g$ = acceleration due to gravity, which is constant at a given locality. $T = \pi\sqrt{l/g}$; since $\pi$ = constant, $T \propto \sqrt{l/g}$, and in a given locality $T \propto \sqrt{l}$. If $l$ = constant, then for any locality $T \propto l\sqrt{g}$.

If $T$ = constant, $gT^2 = \pi^2\,l$; $l \propto g$, $g = \pi^2\,l/T^2$. This equation gives the force of gravity at any locality if $l$ of a simple pendulum vibrating seconds at that locality is known.

At New York, $l = 39.1017$ in. = 3.2585 ft., and $g = 32.16$ ft. The time of vibration of any pendulum at New York = $T\sqrt{l/39.1017} = 0.16\sqrt{l}$. The length of a pendulum at New York, having a given time of vibration is $l = T^2 \times 39.1017$ in.

The time of vibration may be varied by adding a weight or *bob* above the point of suspension, which lengthens time $T$. By varying the height of the upper bob, $T$ is varied.

Let $W$, $w$ = weight of lower and upper bobs, lb., respectively, $D$, $d$ = distance, in., of lower and upper bobs, respectively, from point of suspension. Then $w = W\{(39.1\,D - D^2)/(39.1\,d - d^2)\}$. Thus by adding a second bob, short pendulums may be made to vibrate as slowly as long ones.

**Conical Pendulum.**—A weight suspended by a cord and revolving at a uniform speed in the circumference of a circular horizontal plane whose radius is $r$, the distance of the plane below the point of suspension being $h$, is held in equilibrium by three forces—the tension in the cord, the centrifugal force, which tends to increase the radius $r$, and the force of gravity acting downward. If $v$ = velocity, ft. per sec. of the center of gravity of the weight, as it describes the circumference, $g = 32.16$, and $r$ and $h$ are taken in feet, the time in seconds of performing one revolution is (at New York or other place where $g = 32.16$)

$$t = 2\pi\, r/v = 2\pi\sqrt{h/g}; \qquad h = g\,t^2/4\pi^2 = 0.8146\,t^2.$$

If $t = 1$ second, $h = 0.8146$ foot = 9.775 inches.

**CENTER OF PERCUSSION** is identical with center of oscillation, and is the point at which the percussive action of a blow is the same as if the whole mass of the body were concentrated at the point.

**IMPACT.**—Let $m_1\ m_2$ = mass of two inelastic bodies; $v_1$, $v_2$ = their respective velocities. Then if these two bodies collide, they will move on as one mass with a common velocity $v$. $(m_1 + m_2)v = m_1 v_1 + m_2 v_2$, and $v = (m_1 v_1 + m_2 v_2)/(m_1 + m_2)$. If the bodies move in opposite directions, $v = (m_1 v_1 - m_2 v_2)/(m_1 + m_2)$. If $m_1 v_1 = m_2 v_2$, and the bodies impinge directly from opposite directions, $v = 0$; that is the bodies will be brought to rest.

**The Loss of Energy** resulting from the impact of inelastic bodies is the sum of the energies lost and gained by the bodies respectively.

$$^1/_2\, m_1 v_1^2 + {}^1/_2\, m_2 v_2^2 - {}^1/_2\, (m_1 + m_2)v_2 = {}^1/_2\, m_1(v_1 - v)^2 + {}^1/_2\, m_2(v_2 - v)^2.$$

Example.—Let $m_1 = 10$, $m_2 = 8$, $v_1 = 12$, $v_2 = 15$. $v = \{(10 \times 12) - (8 \times 15)\}/(10 + 8) = 0$.

$$\text{Energy loss} = ({}^1/_2 \times 10 \times 12^2) + ({}^1/_2 \times 8 \times 15^2)$$
$$= \{{}^1/_2 \times 10 \times (12 - 0)^2\} + \{{}^1/_2 \times 8 \times (15 - 0)^2\} = 1620 \text{ ft.-lb.}$$

The lost energy does internal work on the bodies by changing their shape and heating them.

**For Imperfectly Elastic Bodies** of elasticity $e = f_r/f_c$,

$$v'_1 = \frac{m_1 v_1 + m_2 v_2}{m_1 + m_2} - \frac{m_2\, e\,(v_1 - v_2)}{m_1 + m_2}; \qquad v'_2 = \frac{m_1 v_1 + m_2 v_2}{m_1 + m_2} + \frac{m_2\, e\,(v_1 - v_2)}{m_1 + m_2},$$

where $v'_1$ and $v'_2$ = respective velocities of the bodies after impact, $f_r$ = internal force tending to restore shape of body after compression, $f_c$ = force of compression, other notation being as before.

**For Perfectly Elastic Bodies,** $v'_1 - v'_2 = v_2 - v_1$; that is, relative velocities before and after impact are the same, and $m_1 v'_1 + m_2 v'_2 = m_1 v_1 + m_2 v_2$.

# FRICTION *

## 1. THE LAWS OF FRICTION

**References.**—Thomsen, The Practice of Lubrication (McGraw-Hill); Battle, Industrial Oil Engineering (Lippincott); Archbutt and Deeley, Lubrication and Lubricants (Griffin, London); Thurston, Friction and Lost Work (John Wiley & Sons); Kimball and Barr, Elements of Machine Design (John Wiley & Sons).

**FRICTION** is defined by Rankine as that force which acts between two bodies at their surface of contact so as to resist their sliding on each other, and which depends on the force with which the bodies are pressed together.

Friction is either useful or harmful, depending on its relation to the mechanism or process in which it occurs. Examples of useful friction are brakes, self-locking mechanisms, bolted or riveted joints, heaping loose materials, etc. Friction is harmful in bearings, as it wastes power, and in pipes where it retards flow. Friction in static structures tends to preserve them; in brakes it destroys material; in well-lubricated bearings it is accompanied neither by wear of the bearings nor by deterioration of the lubricant.

* Staff revision.

**COEFFICIENT OF FRICTION.**—The ratio of the force required to slide a body along a horizontal plane surface to the weight of the body is called the coefficient of friction. It is equivalent to the tangent of the *angle of repose*, which is the angle of inclination, to the horizontal, of an inclined plane on which the body will just overcome its tendency to slide. The angle usually is denoted by $\theta$, and the coefficient by $f$ or $\lambda$: $f = \tan\theta$. If the inclined surface, Fig. 1*a*, upon which a loaded block rests without motion, is made gradually steeper until the block starts to slide, the angle at which the sliding starts is the angle of repose for static friction. After the motion has begun, if the angle is not reduced, the block usually will accelerate down the incline. If the angle then be reduced until the block slides with uniform velocity, the angle at which this occurs may be used to determine the friction opposing that particular velocity. The angle $\Delta$ shown in Fig. 1*b* is used as a measure of the manner in which granular materials may be heaped. This angle varies widely with the character of the material. Values of $f$ for a wide variety of materials, both at rest and in motion, are given in Table 1.

**FRICTION OF REST AND OF MOTION.**—The force required to start a body sliding is called the friction of rest, and the force required to continue its sliding after having started is called the friction of motion. Except at very low velocities, sliding friction is less than the friction of rest. If $P$ is the force with which two bodies, sliding on each other, are pressed together, their motion is resisted by a force $R$ acting in a direction opposite to the direction of motion, which is called the frictional resistance, and $R = fP$, where $f$ is the coefficient of sliding friction.

**Minimum Starting Friction.**—Starting friction, neglecting acceleration, can be reduced to zero if the surfaces are separated by a liquid of low viscosity, as shown in Fig. 2. Liquid is pumped into the recess at the center of the disc under such pressure that when the flow reaches the edge of the plate the load is supported entirely by a fluid film. This method is used for starting oil film bearings, the lubricating oil being the pressure liquid.

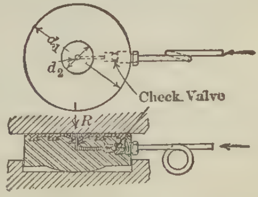

FIG. 2

**Starting Friction of Newly-finished Bearing Surfaces.**—The following summarizes recent (1937) tests of newly finished surfaces to determine the influence of method of finishing on the coefficient of starting friction in the absence of vibration. The tests were made with a babbitt-faced shoe, of 60.7 sq. in. area, scraped to a surface plate, opposed to a close-grained cast-iron surface, finish turned and lapped with fairly coarse carborundum. The surfaces were immersed in light oil, and subjected to a load of over 300 lb. per sq. in. for several hours. The coefficient of starting friction was as high as 0.66. It was reduced to as low as 0.21 by more refined finishes. The lowest coefficients were found when the cast-iron surfaces had been scrubbed by rotation, pressed by a leather-covered block, using lubricating oil impregnated with a very fine abrasive. The direction of motion during test (so long as it is concentric), seems to have little influence on the coefficient of friction.

Some of the values of starting coefficient of friction determined were: Lard oil, load applied for 2 hr., $f = 0.18$; castor oil, load applied for 113 hr., $f = 0.25$; light mineral oil, viscosity 150 Saybolt universal seconds, load applied 14 to 18 hr., $f = 0.30$. Kerosene gave higher values than the mineral oil. The conclusions drawn from the test were: In the absence of vibration, the starting friction coefficient is a function of the newness of the surfaces, of the methods of finishing employed, of the time which the surfaces have been pressed together, of the pressure acting on them, of the nature and viscosity of the lubricating oil in which the surfaces are immersed, and of the area of the smaller of the two faces. When the surfaces are loaded to around 300 lb. per sq. in. and have an area of 60 sq. in., the coefficient of static friction in the absence of vibration may be expected to be below 0.30 for new faces, and below 0.20 for those in service. The influence of electrical vibration is believed to reduce these values 20% or more.

**Influence of Surface Finish on Starting Friction and Friction at Low Speed.**—Howarth's experiments on a low speed and other tests of Kingsbury thrust bearings (*Trans.* A.S.M.E., xli, p. 685, 1919) show the variation, with speed and load, of friction of motion in a small thrust bearing of a mean diameter of 9.375 in., having four babbitt-faced shoes, and a revolving cast-iron runner. The total shoe area was varied from 71.5 sq. in. to 10 sq. in. in order to test pressures ranging from 140 to 1000 lb. per sq. in. In a typical test, the load was 600 lb. per sq. in. Machine oil, of 5.345 Saybolt universal seconds viscosity at the test temperature, was used as lubricant, the surfaces being always submerged. The test was started at 16 r.p.m., speed being reduced gradually to 1/3 r.p.m. The friction coefficient increased gradually, but irregularly, from about 0.0015 at 16 r.p.m. to about 0.132 at 1/3 r.p.m. The speed then was gradually increased without changing the load. The friction coefficients determined for the increasing speeds were much lower than that for decreasing speeds. This was explained by the improvement of bearing surfaces due to the long running at low speed. During these tests friction coefficients for starting from rest were found to vary from 0.15 to 0.20. These values, therefore, may be considered satisfactory for bearing surfaces that have been in operation for some time under favorable conditions in which a number of starts and stops have gradually brought the surfaces to a condition favorable to such starting when immersed in an oil bath.

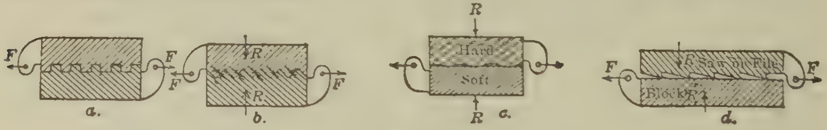

FIG. 3

**Maximum Friction.**—When two metals are sweated or brazed together, the force required to separate them transversely at the joint is less a function of the pressure than of the transverse shearing strength of the metal bond. This might be a combination of the breaking of the bond between the soft and hard material and the actual shearing of the soft material on itself. The force required for such separation cannot consistently be expressed by means of a coefficient of friction.

INTERLOCKING FRICTION.—If two surfaces interlock, as in a square thread screw, Fig. 3*a*, the force required to slide one on the other depends more on strength of the materials and proportion of interlocking than on the load acting between them. If the surfaces are free to move vertically against a load, Fig. 3*b*, the force required to slide them laterally would be a combination of sliding friction and lifting of the load. When an irregular hard surface presses against a soft one, Fig. 3*c*, the resistance offered to sliding one over the other will depend on the normal load, on the sliding friction, on resistance to deformation of the soft surface, and on the strength of the softer surface as it might be broken down because of interlocking. Fig. 3*d* illustrates abrading frictional resistance to sliding of one surface over another, as a saw or file. The greater the normal pressure on the saw or file, the more will it cut into the lower block and the greater will be the resistance offered to transverse motion.

INFLUENCE OF VIBRATION.—Tests to determine starting friction show coefficients of friction to be much higher in the absence of vibration than in its presence, and that friction decreases as the disturbance by vibration increases. Vibration similarly reduces the friction of motion so long as metallic contact is present in any considerable degree. With perfect lubrication, bearing surfaces are completely separated by lubricating films, and vibration does not appear to change the coefficient of friction of motion.

**ROLLING FRICTION** is the force required to roll a cylindrical or spherical body on a plane or on a curved surface. It depends on the nature of the surfaces and on the force with which they are pressed together, but is different from ordinary, or sliding, friction.

Rolling friction is a consequence of the irregularities of form and the roughness of surface of bodies rolling one over the other. Its laws are not yet definitely established in consequence of the uncertainty which exists in experiment as to how much of the resistance is due to roughness of surface, how much to original and permanent irregularity of form, and how much to distortion under the load.

**Coefficients of Rolling Friction.**—Let $R$ = resistance applied at the circumference of the wheel, $W$ = total weight, $r$ = radius of the wheel, and $f$ = a coefficient. Then $R = fW \div r$. The value of $f$ is very variable. Coulomb gives 0.06 for wood, 0.005 for metal, where $W$ is in pounds and $r$ in feet. Tredgold made the value of $f$ for iron on iron 0.002. For wagons on soft soil Morin found $f$ = 0.065, and on hard smooth roads 0.002.

A Committee of the Society of Arts (Clark, R. T. D.) reported a loaded omnibus to exhibit a resistance on various loads as below:

| Pavement | Speed per hr. | Coefficient | Resistance |
|---|---|---|---|
| Granite | 2.87 miles | 0.007 | 17.41 per ton |
| Asphalt | 3.56 " | 0.0121 | 27.14 " |
| Wood | 3.34 " | 0.0185 | 41.60 " |
| Macadam, graveled | 3.45 " | 0.0199 | 44.48 " |
| Macadam, granite, new | 3.51 " | 0.0451 | 101.09 " |

Thurston gives the value of $f$ for ordinary railroads, 0.003; well-laid railroad track, 0.002; best possible railroad track, 0.001. The friction of pneumatic tires on roads is discussed in Kent's Mechanical Engineers' Handbook—Power, p. 14–55, forming Vol. 2 of this series.

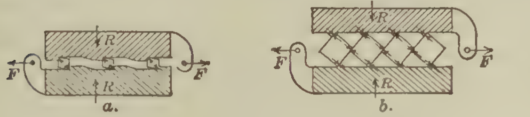

FIG. 4

**GRANULAR FRICTION.**—The friction required to move one surface over another when granular material is placed between them probably is a combination of several kinds of interaction. The simplest condition is that in which the granular particles turn over and over without interference (Fig. 4*a*). Fig. 4*b* indicates how the granular particles may become interlocked so they will abrade each other and may cut both surfaces when motion occurs. Fig. 4*c* represents granular particles embedded in the softer surface and acting as cutters when moved on the harder surface.

**SKIDDING FRICTION** results from slipping of rubber tires on a pavement. The friction depends on the type of tire surface and conditions of the pavement. With rough pavement and smooth tires, high spots on the pavement will penetrate any film that is formed and project into the rubber, thus diminishing tendency to skid. With a smooth pavement and tires, the film of water, clay or pulpy material found on roads, will completely separate the surfaces. The tire then will slide freely in any direction. See Fig. 5*a*.

In the non-skid tire, Fig. 5*b*, the rubber surface is broken up into small faces, with deep grooves between. The theory of lubrication shows that the thickness of film formed when sliding occurs decreases as the supporting area for a given load decreases, and the films will more quickly leak from between the surfaces and permit them to come together. On rough roads the difference between the action of smooth and non-skid tires is small. Even non-skid tire surfaces are apt to slip on pulpy material or on clay, since such materials build up much thicker films than are possible with clear water.

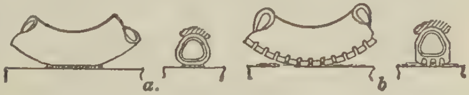

FIG. 5

**FLUID FRICTION** includes the frictional resistance to motion of: Fluids in containers, as the flow of water or gas in pipes; of solid bodies completely separated by a film of fluid, as a perfectly lubricated bearing; of solid partially or wholly immersed in a fluid, as a boat moving through water.

**LAWS OF FRICTION.**—The laws of friction, first formulated by Morin about 1830, have been modified from time to time by the work of later experimenters. The following paragraphs form a brief statement of the generally-accepted laws, based on present-day practice.

**Laws of Friction for Unlubricated Surfaces.**—1. Friction varies approximately as the normal pressure with which the rubbing surfaces are pressed together.

2. Friction is approximately independent of the area of the surfaces, but is slightly greater for small surfaces than for large surfaces.

3. Friction decreases with increase of velocity, except at very low velocity, and with soft surfaces.

**Laws of Friction for Lubricated Surfaces.**—*Perfect Lubrication, i.e.*, surfaces completely separated by a film of lubricant:

4. The coefficient of friction is independent of the materials of the surfaces.

5. The coefficient of friction varies directly with the viscosity of the lubricant, which varies inversely with temperature of the lubricant.

6. The coefficient of friction varies inversely as the unit pressure, and directly as the velocity.

7. The coefficient of friction varies inversely as the mean film thickness of the lubricating medium.

8. Mean film thickness varies directly with velocity and inversely as the temperature and unit pressure.

For a full discussion of the friction of perfectly lubricated bearings, see p. 13–44.

*Imperfect Lubrication, i.e.*, surfaces partially separated by a film of lubricant, may range from almost complete separation of the surfaces to almost complete contact.

9. The coefficient of friction increases with increase of pressure between surfaces.

10. The coefficient of friction decreases with increase of relative velocity between the surfaces.

**Laws of Fluid Friction.**—Thurston states that for all fluids, whether liquid or gaseous, the resistance is: 1. Independent of the pressure between the masses in contact; 2. Directly proportional to the area of rubbing-surface; 3. Proportional to the square of the relative velocity at moderate and high speeds, and to the velocity nearly at low speeds; 4. Independent of the nature of the surfaces of the solid against which the stream may flow, but dependent to some extent upon their degree of roughness; 5. Proportional to the density of the fluid, and related in some way to its viscosity.

Fluid friction, as related to the flow of liquids in pipes, is discussed in Kent's Mechanical Engineers' Handbook—Power, p. 4–56, forming Vol. 2 of this series.

**LOW FRICTION COEFFICIENTS.**—Friction coefficients frequently are as low as 0.001 in journal and thrust bearings in operation with perfect lubrication. Much lower values have been obtained experimentally. Fig. 6 shows coefficients obtained by S. J. Needs in the laboratory of Albert S. Kingsbury, using a 120-deg. fitted bearing 4 in. wide,

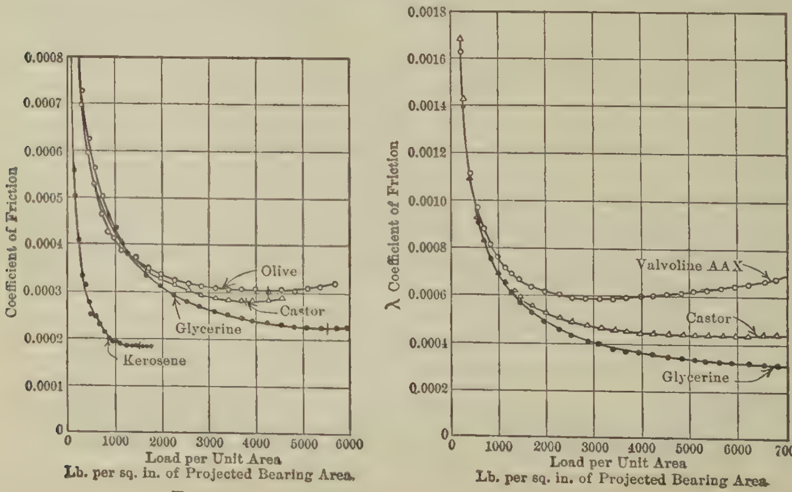

Fig. 6 Fig. 7

Variation of Viscosity with Pressure

4 in. diameter. The value 0.000183 is the lowest known value obtained in a bearing lubricated by oil.

Fig. 7 indicates that the viscosity of the lubricant may increase considerably with pressure. The three oils had identical viscosities at the beginning of the test, were subjected to the same series of loads, and run at the same speed of 11.06 r.p.m. The Valvoline AAX oil showed the greatest increase of viscosity with load. The least increase was shown by glycerine. Castor oil viscosity increased an intermediate amount. In these tests the bearing always operated under fluid film conditions, and the bearing surfaces were completely separated.

## 2. FRICTION OF MACHINE ELEMENTS

**FRICTION OF BEARINGS.**—For a detailed discussion of the friction of bearings, see pp. 13–03 to 13–58. The following data, from various sources, are for general guidance only. For design, in cases where friction is an important factor, reference should be made to the pages above cited.

**FRICTION OF JOURNALS.**—The friction of journals usually is expressed in terms of units of projected area, that is, $d \times l$, where $d$ = diameter and $l$ = length of journal. Unwin states that the friction of journals must lie between $\pi fP/2$ and $4fP/\pi$, where $f$ = coefficient of friction and $P$ = load on journal. For journals in ordinary condition the value of $fP$ usually is sufficiently accurate. Values of $f$ vary according to different authorities. Unwin gives the following:

| Authority. | $f$ | Conditions. |
|---|---|---|
| Morin | 0.05 to 0.07 | Good journals, well lubricated |
| Rühlmann & Waltjen | 0.02 to 0.03 | Wrought-iron on gun metal |
| Kirchweger | 0.009 to 0.01 | " " " white metal* |
| " | 0.014 | " " " gun metal* |
| Bokelberg & Welkner | 0.0028 | Small loads, low velocities† |
| " " | 0.013 | Heavy loads, high velocities† |

The work lost in friction, in ft.-lb. per minute is $W = fP\pi n(d/12)$, where $n$ = rev. per minute, $d$ = diam. of journal, in., other notation as above.

The friction of a journal is influenced by the character and quantity of lubrication. Below are the results of experiments on lubricated journals.

**Experiments on Friction of a Journal Lubricated by an Oil-bath** (reported by the Committee on Friction, *Proc.* Inst. M. E., Nov., 1883) show that the absolute friction, that is, the absolute tangential force per square inch of bearing, required to resist the tendency of the brass to go round with the journal, is nearly a constant under all loads, within ordinary working limits. Most certainly it does not increase in direct proportion to the load, as it should do according to the ordinary theory of solid friction. The results of these experiments seem to show that the friction of a perfectly lubricated journal follows the laws of liquid friction much more closely than those of solid friction. They show that under these circumstances the friction is nearly independent of the pressure per square inch, and that it increases with the velocity, though at a rate not nearly so rapid as the square of the velocity. See Table 2.

The experiments indicate a great diminution in the friction as the temperature rises. With lard-oil, at a speed of 450 r.p.m., the coefficient of friction at 120° F. is only one-third of the coefficient at 60° F. See Table 3.

In the experiments, the journal was of steel, 4 in. diameter and 6 in. long. A gun-metal brass, embracing somewhat less than half the circumference of the journal, rested on its upper side, on which the load was applied. When the bottom of the journal was immersed in oil, and the oil therefore carried under the brass by rotation of the journal, the greatest load carried with rape-oil was 573 lb. per sq. in., and with mineral oil 625 lb.

In experiments with ordinary lubrication, the oil being fed in at the center of the top of the brass, and a distributing groove being cut in the brass parallel to the axis of the journal, the bearing would not run cool even with a load of but 100 lb. per sq. in., the oil being pressed out from the bearing-surface and through the oil-hole, instead of being carried in. Introducing the oil at the sides through two parallel grooves, gave apparently satisfactory lubrication, but the bearing seized at a pressure of 380 lb. per sq. in.

When the oil was introduced through two oil-holes, one near each end of the brass, and each connected with a curved groove, the brass refused to take its oil or run cool, and seized with a load of only 200 lb. per sq. in.

With an oil-pad under the journal feeding rape-oil, the bearing fairly carried 551 lb. Mr. Tower's conclusion from these experiments is that the friction depends on the quantity and uniformity of distribution of the oil, and may be anything between the oil-bath results and seizing, according to the perfection or imperfection of the lubrication. The lubrication may be very small, giving a coefficient of $1/100$; but it appeared as though it could not be diminished and the friction increased much beyond this point without imminent risk of heating and seizing. The oil-bath probably represents the most perfect lubrication possible, and the limit beyond which friction cannot be reduced by lubrication. The experiments show that with speeds of from 100 to 200 ft. per minute, by properly proportioning the bearing-surface to the load, it is possible to reduce the coefficient of friction to as low as 0.001. A coefficient of 0.00066 is easily attainable, and probably is frequently attained, in ordinary engine-bearings in which the direction of the force is rapidly alternating and the oil has an opportunity to get between the surfaces, while the duration of the force in one direction is not sufficient to allow time for the oil film to be squeezed out.

Observations on the behavior of the apparatus gave reason to believe that with perfect lubrication the speed of minimum friction was from 100 to 150 ft. per minute, and that this speed of minimum friction tends to be higher with an increase of load, and also with less perfect lubrication. By the speed of minimum friction is meant that speed in approaching which from rest the friction diminishes, and above which the friction increases. Table 4 gives coefficients of friction as determined in these experiments.

Comparative friction of different lubricants under same circumstances, temperature 90° F., oil-bath: sperm-oil, 100; rape-oil, 106; mineral oil, 129; lard, 135; olive oil, 135; mineral grease, 217.

**Value of Anti-friction Metals.**—According to Prof. J. E. Denton the various white metals available for lining brasses do not afford coefficients of friction lower than can be obtained with bare brass, but they are less liable to "overheating," because of the superiority of such material over bronze in ability to permit of abrasion or crushing, without excessive increase of friction. Thurston (Friction and Lost Work) says that gun-bronze, Babbitt, and other soft white alloys have substantially the same friction; in other words, the friction is determined by the nature of the unguent and not by that of the rubbing-surfaces, when the latter are in good order. The soft metals run at higher temperatures than the bronze. This, however, does not necessarily indicate a serious defect, but simply deficient conductivity. The value of the white alloys for bearings lies mainly in their ready reduction to a smooth surface after any local or general injury by alteration of either surface of form. See Bearing metals, pp. 4–62 to 4–67.

**Ball Bearings.**—The friction of ball bearings varies with the design and construction of the bearing. In general, it decreases with increase of load, and is independent of speed and temperature. Stribeck found the coefficient of friction in one type of bearing at 65 r.p.m. to vary from $f = 0.0033$ with a load of 838 lb. to $f = 0.0015$ with a load of 6614 lb. At 780 r.p.m. the same bearings showed $f = 0.0037$ and $f = 0.0013$, respectively, at 838 lb. and 6614 lb. loads.

Goodman gives the following ranges for $f$ in various types of ball bearings: Cylindrical, 2-point bearing, $f = 0.0012$ to $0.0018$; thrust, 2-point bearing, $f = 0.0008$ to $0.0012$; thrust, 3-point bearing, $f = 0.0018$ (average); thrust, 4-point bearing, $f = 0.0055$.

**Roller Bearings.**—The coefficient of friction of roller bearings decreases with increase of load and with increase of temperature. It seems to be independent of the speed. Goodman gives values at loads of 2000 and 10,000 lb. respectively, of $f = 0.0131$ to $0.0072$ for 40 r.p.m., and of $f = 0.0053$ to $0.0024$ for 400 r.p.m.

**BELTING.**—For data on the coefficient of friction of belting, see pp. 24–15 and 24–36.

**GEARING.**—The friction of gearing depends on the type, the material of the gears, the quality of workmanship, quality of lubrication, and the form of the teeth. Values given below should be used with caution, as they are applicable only under conditions identical with those under which the determination was made.

**Spur Gears.**—Wilfred Lewis gives the following as the friction losses $F$ of various types of spur gears, in which $p$ = circular pitch: 20-deg. stub gear, addendum of $0.24\,p$, $F < 1\%$; $22\,{}^1/_2$-deg. gear, addendum of $0.28\,p$, $F = 1\%$ approx.; $14\,{}^1/_2$-deg. gear, addendum of $0.32\,p$, $F = 1.3\%$ approx. Other investigators report friction losses of cut gears in the neighborhood of 1%. The length of addendum has greater effect on the friction than has the angle of obliquity.

**Bevel Gears.**—Friction losses have been reported by various investigators, ranging from 1% under exceptionally good conditions of workmanship and lubrication to 8.6% under less favorable conditions.

**Helical Gears.**—Friction losses in helical gears are composed of the tooth friction losses, which correspond to those of spur gears, and the losses resulting from the transverse sliding of the teeth on each other. The ratio $F_s$ of lost work, due to this latter cause, to the useful work may be expressed as

$$F_s = \{\sin \alpha(\beta + \theta)/\sin \beta \sin (\alpha + \theta)\} - 1$$

in which $\alpha$ and $\beta$ are, respectively, the helical angles of the gears and $\theta$ is the angle of repose, determined from the coefficient of friction, *i.e.*, $f = \tan \theta$.

**Worm Gearing.**—Let $\beta$ = angle of inclination of worm thread to its axis, $P$ = force acting on pitch line of worm in the plane of rotation, $R$ = resistance acting at pitch line of worm-wheel in its plane of rotation, $\theta$ = angle of repose of metal of worm on metal of wheel, $f$ = coefficient of friction = $\tan \theta$, $r_1$ = radius of worm = $1.5\,p$ to $3\,p$ usually, $r_2$ = radius of wheel, $p$ = pitch of teeth of wheel, and $p/n$ = axial pitch of worm, $n$ being the number of threads on the worm. Then

$$\frac{P}{R} = \frac{1 + f \tan \beta}{\tan \beta - f} = \cot (\beta - \theta)$$

$$\text{Efficiency} = \frac{\cot \beta}{\cot (\beta - \theta)} = \left(1 - f\frac{np}{2\pi r_1}\right) \div \left(1 + f\frac{r_1}{np}\right).$$

Taking $f = 0.15$, Efficiency $= np \div (np + r_1)$, approximately.

**Friction Gearing.**—See p. 14–03.

**FRICTION OF HYDRAULIC PLUNGER PACKING.**—Hütte (15th edition, vol. 1, p. 202) says: "For stuffing-boxes with hemp, cotton or leather packing, with water pressures between 1 and 50 atmospheres, the frictional loss depends on the water pressure, the circumference of the packed surface, and a coefficient $\mu$, which is constant for this range of pressure. The loss is independent of the depth of stuffing-box or leather ring, and is given by the formula $F = Kpd$, where $F$ = total frictional loss, lb., $p$ = pressure, lb. per sq. in., $d$ = diameter of plunger, in. $K$ is a coefficient which depends on the kind and condition of the packing, and is given as follows for various cases:

For cotton or hemp, loose or braided, dipped in hot tallow, plungers smooth, glands not pulled down too tight, packing therefore retaining its elasticity, dimensions such as usually occur, $K = 0.072$.

Same conditions, after packing is some months old, $K = 0.132$.

Materials the same, but with hard packing, unfavorable conditions, etc., $K$ = as much as 0.299.

Leather packing, soft leather, well made, etc., $K = 0.036$ to $0.084$.

Hard, stiffly tanned leather, $K = 0.12$ to $0.156$.

Unfavorable conditions, rough plungers, gritty water, etc., $K$ = up to 0.239.

Weisbach-Hermann, in Mechanics of Hoisting Machinery, gives a formula which when translated into the same notation as the one in Hütte is

$$F = 0.0312\,pd \text{ to } 0.0767\,pd.$$

Since the total pressure on a plunger is ${}^1/_4\,\pi d^2\,p$, the ratio of the loss of pressure to the total pressure is $K\,p\,d\,/\,{}^1/_4\,\pi\,d^2\,p$, or using the extreme values of $K$, 0.0312 and 0.299, the ratio ranges from $0.04/d$ to $0.38/d$, or from 4 to 38% divided by the diameter in inches.

Walter Ferris (*Am. Mach.*, Feb. 3, 1898) derives from the formula given above the following formula for the pressure produced by a hemp-packed hydraulic intensifier made with two plungers of different diameters:

$$p_2 = p_1\{(A - KD) \div (a + kd)\},$$

where $p_2$ = pressure per sq. in. produced by the intensifier, $p_1$ = initial pressure, $A$ = area and $D$ = diam. of the larger plunger, $a$ = area and $d$ = diam. of the smaller plunger, and $K$ an experimental coefficient. He gives the following results of tests of an intensifier with a small plunger 8 in. diam. and two large plungers, 14 1/4 and 17 3/4 in., either one of which could be used as desired.

| | | | | |
|---|---|---|---|---|
| Diam. of large plunger, in. | 14 1/4 | 14 1/4 | 17 3/4 | 17 3/4 |
| Initial pressure, lb. per sq. in. | 285 | 475 | 335 | 350 |
| Intensified pressure, lb. per sq. in. | 750 | 1450 | 1450 | 1510 |
| Intensified if there were no friction | 905 | 1505 | 1650 | 1725 |
| Intensified calculated by formula* | 806 | 1433 | 1572 | 1643 |
| Efficiency of machine | 0.83 | 0.965 | 0.88 | 0.875 |

* Assuming $K$ = 0.2. Efficiency calculated by formula in each case = 0.953.

**FRICTION OF KEYS AND COTTERS.**—In a taper key, the angle between the tapered sides of which is $\alpha$, the force required to drive the key home is

$$F = P\{\tan(\theta + \alpha) + \tan\theta\},$$

where $P$ = pressure on the key normal to one of the tapered sides, and $\theta$ = angle of repose of the surfaces in contact.

The force required to drive the key out is

$$F_1 = P\{\tan(\theta - \alpha) + \tan\theta\}.$$

The limiting value of $\alpha$ is $2\theta$, for if $\alpha > 2\theta$ the key will not remain in position. If $f$ = 0.08, $\theta$ = 4.5 deg. The greatest angle of taper, therefore, is 9 deg. or a taper of approximately 1 in 7. Similarly for cotters, where $\alpha_1$, and $\alpha_2$, respectively, are the angles made by the two edges of the cotter with a center line normal to the line of pressure.

$$F = P\{\tan(\theta + \alpha_1) + \tan(\theta + \alpha_2)\},$$

and

$$F_1 = P\{\tan(\theta - \alpha_1) + \tan(\theta - \alpha_2)\}.$$

As before, the cotter will slip out if $(\alpha_1 + \alpha_2) > 2\theta$, which gives a limiting value of $(\alpha_1 + \alpha_2)$ = 9 deg. when $f$ = 0.08.

**FRICTION OF ROPE SHEAVES.**—Unwin gives $f$ = 0.28 for rope on a metal pulley. With ropes in grooves whose sides make an angle of 45 deg. the pressure between the rope and the sides of the groove is greater than the force pressing the rope into the groove, the ratio being $(\operatorname{cosec}\theta/2):1$, where $\theta$ = angle of inclination of groove. The actual coefficient of friction of a rope in a sheave groove then is

$$f = 0.28 \times \operatorname{cosec} {}^1/_2\,\theta,$$

giving for a 45-deg. groove $f$ = 0.7.

**FRICTION OF SCREWS.**—See also p. 8–11. The coefficient of friction of square thread screws 1.425 in., outside diam., 0.33 in. pitch was determined by Kingsbury to range from $f$ = 0.009 to 0.25 with lard oil lubrication, $f$ = 0.11 to 0.19 with heavy machinery oil, and $f$ = 0.03 to 0.15 with heavy oil and graphite. Variation in axial pressure apparently had no effect on values of $f$, nor did $f$ change appreciably with variation of the metals in contact.

**FRICTION OF STEAM ENGINES.**—For data on the friction of steam engines, see Kent's Mechanical Engineers' Handbook—Power, p. 7–28, forming Vol. 2 of this series.

**FRICTION OF V GUIDES.**—Let $P$ be the force pressing a V-shaped block into V-guides, the angle between the faces of the guides being $\beta$. The frictional resistance $R$ to the movement of the block along the guides will be

$$R = fP/\sin({}^1/_2\,\beta),$$

where $f$ = coefficient of friction between the metals of the guides and blocks.

## SCREWS AND SCREW FASTENINGS

**CLASSIFICATION.**—Screws and bolts may be classified, according to use, into two general classes: A. Screws for transmitting power. B. Screw fastenings. Class B may be further subdivided into: 1. Bolts; 2. Studs; 3. Machine screws; 4. Cap-screws or Tap-bolts; 5. Set-screws; 6. T-head bolts; 7. Coupling bolts; 8. Hook bolts; 9. Automobile bolts; 10. Carriage bolts; 11. Stove bolts; 12. Expansion bolts; 13. Foundation bolts; 14. Eye-bolts; 15. Stay-bolts; 16. Patch bolts; 17. Wood screws; 18. Lag screws and other special screws and bolts.

### 1. FORMS OF THREAD

The form of thread depends on the service required and on the engineering standards of the country in which the thread is used. In general, the full V-thread and the modified V-thread are best adapted for fastenings. These combine strength and cheapness; the inefficiency of the V-thread in transmitting power lessens the liability of unscrewing.

**POWER-TRANSMISSION THREADS.**—Three forms of threads are adapted to the transmission of power: *a.* The square thread, Fig. 1, has the highest efficiency in transmitting power. It is expensive to make and is not easily compensated for wear. *b.* The so-called Acme thread, Fig. 2, is not so expensive to cut as the square thread, and wear can be compensated by means of a longitudinally split nut. Its efficiency in transmitting power is less than that of the square thread. *c.* The buttress thread, Fig. 3, is used for the transmission of power in one direction only. The driving face is perpendicular to the axis of the screw; the back face makes an angle, usually 45 deg., with the axis. This combination gives the efficiency of the square thread and the strength of the V-thread.

Besides the threads referred to, the standard pipe thread may be considered a form of fastening. See **Kent's Mechanical Engineers' Handbook—Power, p. 5–40, forming Vol. 2 of this series.**

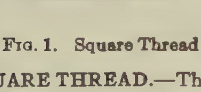

**Fig. 1. Square Thread**

**Fig. 2. Acme Thread**

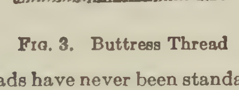

**Fig. 3. Buttress Thread**

**SQUARE THREAD.**—The proportions of square threads have never been standardized, but the practice of Wm. Sellers & Co. is given in Table 1.

**THE ACME SCREW THREAD.**—The Acme thread is an adaptation of the commonly-used style of worm thread and is intended to take the place of the square thread. It is a little shallower than the worm thread, but the same depth as the square thread, and much

stronger than the latter. The angle of the thread is 29 deg. The proportions are given by the following formulas:

$$p = \text{pitch} = (1/\text{No. of threads per inch}) \quad [1]$$

$$d = \text{depth} = 0.5p + 0.010 \quad [2]$$

$$f = \text{flat on top of thread} = p \times 0.3707 \quad [3]$$

$$f' = \text{flat at bottom of thread} = p \times 0.3707 - 0.0052 \quad [4]$$

See also Fig. 2 and Table 2.

## 2. SCREW THREAD STANDARDS

The screw threads generally used in the United States conform to the dimensions of the American Standard Screw Threads as published by the American Standards Association. Tables 3 to 11 show the dimensions and tolerances of the various classes of threads covered by this standard. Five series of screw threads are covered, differing in the diameter-pitch relations of the threads, but all using the American National Standard form of thread.

**FORM OF THREAD.**—The American National Standard form of thread profile is the form previously known as the United States Standard or Sellers profile. The basic angle of thread between the sides of the thread, measured in an axial plane, is 60 deg. The basic width of flat at the root and crest of the thread is

$$F = {}^1/_8\, p = 0.125\, p \quad [5]$$

where $F$ = width of flat, and $p$ = pitch of thread, both in inches.

The basic depth of the thread form is

$$h = 0.649519\, p = 0.649519/n \quad [6]$$

where $h$ = depth of thread, in.; $n$ = number of threads per inch.

**Clearance in Nut at Minor Diameter.**—The screw thread in the nut is so truncated that the basic depth of the thread is reduced by one-sixth or more, depending on the size and pitch, to provide a clearance at the minor diameter of the thread.

**Clearance in Nut at Major Diameter** is provided by decreasing the depth of the truncation triangle any desired amount down to one-third of its theoretical value.

**DEFINITIONS.**—The more important terms are defined below. See also Figs. 4 and 5.

**Major Diameter** is the largest diameter of a screw thread. It applies both to internal and external threads.

**Minor Diameter** is the smallest diameter of a screw thread. The term applies to both internal and external threads.

**Pitch Diameter** is the diameter of an imaginary cylinder whose surface would pass through the threads at such points as to make equal the width of the threads and the width of the spaces cut by the surface of the cylinder.

**Pitch** is the distance from a point on a screw thread to a corresponding point on the next thread, measured parallel to the axis. Pitch, in inches, equals (1/ No. of threads per inch).

**Lead** is the distance a screw thread advances axially in one turn. On a single-thread screw, lead and pitch are identical. On double-thread screws, lead is twice the pitch. On triple-thread screws, lead is three times the pitch, etc.

**Angle of Thread** is the angle included between the sides of the thread, measured in an axial plane.

**Helix Angle** is the angle made by the helix of the thread, at the pitch diameter, with a plane perpendicular to the axis. The tangent of the helix angle $S = L/\pi E$, where $L$ = lead, and $E$ = the pitch diameter.

**Crest** is the top surface joining the two sides of a thread.

**Root** is the bottom surface joining the sides of two adjacent threads.

**Side** is the surface of the thread connecting the crest with the root.

**Depth of Thread** is the distance between crest and root, measured normal to the axis.

**Length of Engagement** is the length of contact between two mating parts, measured axially.

**Depth of Engagement** is the depth of thread contact of two mating parts, measured radially.

**DEFINITIONS RELATING TO FITS.**—**Basic Size** is the theoretical or nominal standard size from which all variations are made.

**Crest Clearance** is the space between the crest of a thread and the root of its mating thread.

**Allowance** is an intentional difference in the dimensions of mating parts. It is the minimum clearance or the maximum interference between mating parts. See Table 4.

**Tolerance** is the amount of variation permitted in the size of a part. In Tables 5 to 11 tolerance is the difference between the maximum and the minimum dimensions given.

**Limits** are the extreme permissible dimensions of a part.

**Fit** is the relation between two mating parts with reference to ease of assembly. Quality of fit depends both on the relative size and the quality of finish of mating parts.

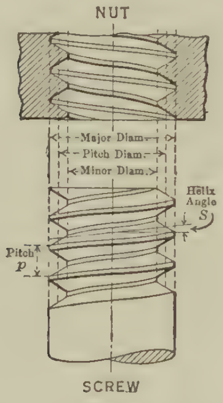

Fig. 4

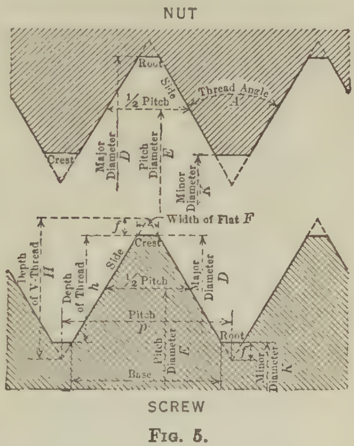

Fig. 5.

**SCREW THREAD SERIES.**—The five series of screw threads are as follows:

**Coarse Thread Series** is the former United States Standard, supplemented in the sizes below $1/4$ in. by a part of the standard proportions for machine screws established by the A.S.M.E. in 1907. General dimensions are given in Table 3. This series is recommended for general use.

**Fine Thread Series** is in accordance with the former regular screw thread series established by the S.A.E. in 1911, supplemented below $1/4$ in. by sizes selected from the standard proportions for machine screws established by the A.S.M.E. in 1907. General dimensions are given in Table 3.

**8-pitch-thread Series** is a series in which the number of threads per inch is constant at 8 irrespective of the diameter. Used on bolts for high-pressure pipe flanges, cylinder-head studs, and cylinder fastenings against pressure, in which it is required that an initial tension be set up in the fastening by elastic deformation of the fastening. To procure proper initial tension it is not practicable that the pitch should increase with the diameter of the thread because the torque required to assemble the fastening would be excessive. Limiting dimensions are given in Table 10.

**12-pitch-thread Series.**—12-pitch threads from $1/2$ in. to and including 1 $3/4$ in. are used in boiler practice. This requires that a worn stud hole be retapped with a tap of the next larger size, the increment being $1/16$ in. throughout most of the range. These threads are widely used also in machine construction for thin nuts on shafts and sleeves. Shoulder diameters should be limited to steps of not less than $1/8$ in. 12-pitch is the coarsest pitch in general use that will permit a threaded collar which screws on a threaded shoulder to fit over a shaft, the difference between shoulder and shaft being $1/8$ in.

**16-pitch-thread Series** is a uniform-pitch series for applications requiring a very fine thread. It is intended primarily for use on threaded adjusting collars and bearing retaining nuts. Limiting dimensions are given in Table 11.

**Table 3.—General Dimensions of Coarse-thread and Fine-thread Series Screw Threads**
(A.S.A. Standard B1.1—1935) For Limiting Dimensions, see Tables 5 to 9

| Size | Threads per Inch, $n$ | Basic Diameters | | | Thread Data | | | | | |

* This column is given to seven decimal places for computation purposes only.

† Equals $\pi K^2/4$. Basic areas are given for roughly computing ultimate strength of thread. Actual strength, computed from ultimate strength of the material, will depend on actual cross-sectional area at root of thread and an increment contributed by the thread itself.

**SCREW THREAD FITS.**—The four classes of screw thread fits covered by the American Standard range from Class 1, the loosest, to Class 4, the closest. They are produced by the application of specific tolerances, or tolerances together with allowances. Allowances are applicable, in the case of the screw only, to the basic pitch diameter of the thread which is the same for both external and internal threads of like size and pitch. Tolerances are applied *plus* to the hole, and *minus* to the screw. The several classes of fits are described below.

**Class 1 Fit.**—A screw and hole threaded to Class 1 specifications never will produce a close fit, and there always will be " play " or looseness. This fit is recommended for screw thread work where clearance between mating parts is essential for rapid assembly, and where shake or play is unobjectionable. In the Class 1 fit, the maximum nut is basic and the maximum screw is below basic. The major diameter and pitch diameter of the maximum screw are below the basic dimensions by the amount of the allowance specified in Table 4. The tolerance on the nut is *plus*. The tolerance on the screw is *minus*. Pitch-diameter tolerances for a screw or nut of a given pitch are given in Table 4. Limiting dimensions are given in Table 5.

**Class 2 Fit.**—A screw and hole threaded to Class 2 specifications may vary from a fit with no play when pitch diameters of the mating parts are at their common basic value, to a fit with some play in the case of a minimum screw and a maximum hole, when the total pitch diameter tolerance has been applied to both parts. This fit represents a high quality of screw thread product. It is recommended for the majority of interchangeable

* Allowances apply to screw only; the nut is basic.

† Variation in lead between any two threads not farther apart than the length of engagement which would absorb one-half the pitch diameter tolerance.

‡ Variation in half-angle which would absorb one-half the pitch diameter tolerance.

§ Allowance is zero.

¶ Negative allowance applies to screw only; the nut is basic.

screw thread work. In the Class 2 fit the minimum nut and the maximum screw are basic. The tolerance on the nut is *plus* and on the screw *minus*. Allowance between pitch diameters of maximum screw and minimum nuts is zero for all pitches and diameters. Pitch diameter tolerances for screw or nut of a given pitch are specified in Table 4. Limiting dimensions are given in Tables 6 and 10.

**Class 3 Fit.**—A screw and hole threaded to Class 3 specifications may vary from a fit with no play, when pitch diameter of both mating parts is at their common basic value, to a fit with a play of about 70% of that allowed under Class 2. This is obtained with a minimum screw and a maximum hole when the total Class 3 pitch diameter tolerance has been applied to both parts. Class 3 fits are recommended only where the high cost of precision tools, and continual checking of tools and products, is warranted. In the Class 3 fit, the minimum nut and the maximum screw are basic. The tolerance on the nut is *plus* and on the screw is *minus*. The allowance between pitch diameters of maximum screw and minimum nut is zero for all pitches and diameters. Pitch diameter tolerances for screw or nut of a given pitch in the coarse- and fine-thread series are specified in Table 4. Limiting dimensions for the coarse- and fine-thread series are given in Table 7

* Below basic; see Class 1 Fits, p. 9–07.

† Dimensions are figured to the intersection of the worn tool arc with a center line through crest and root. Minimum flat at root equals 1/8 *p*.

‡ Basic diameter.

§ Dimensions given are produced only with tap having theoretically sharp corners. Threaded holes must not reject correct basic "Go" gage through interference between gage and rounded root of thread in hole due to worn tap. Minimum flat at root equals 1/24 *p*.

¶ The tolerances specified, *i.e.* (max. pitch diam. – min. pitch diam.), are cumulative, and include variations in lead and angle.

* Basic diameter. † Threaded portion only of unfinished hot-rolled material.

‡ Dimensions are figured to the intersection of the worn tool arc with a center line through crest and root. Minimum flat at root equals $1/8\ p$.

§ Dimensions given are produced only with tap having theoretically sharp corners. Threaded hole must not reject correct basic "Go" gage through interference between gage and rounded root of thread in hole due to worn tap. Minimum flat at root equals $1/24\ p$.

¶ The tolerances specified, *i.e.* (max. pitch diam. − min. pitch diam.), are cumulative and include variations in lead and angle.

* Basic diameter.

† Above basic; see Class 4 Fit, p. 9-13.

‡ Dimensions are figured to the intersection of the worn tool arc with a center line through crest and root. Minimum flat at root = 1/8 $p$.

§ Dimensions given are produced only with tap having theoretically sharp corners. Threaded hole must not reject correct basic "Go" gage through interference between gage and rounded root of thread in hole due to worn tap. Minimum flat at root = 1/24 $p$.

¶ The tolerances specified, *i.e.* (max. pitch diam. − min. pitch diam.), are cumulative, and include variations in lead and angle.

* Pitch $p$ = 0.1250 in.; basic depth of thread $h$ = 0.08119 in.

† Basic diameter.

‡ Dimensions are figured to intersection of worn tool arc with center line through crest and root. Minimum flat at root = $1/8\, p$ = 0.01562 in.

§ Dimensions given are allowable only with tap having theoretically sharp corners. Threaded hole must not reject correct basic "Go" gage through interference between gage and rounded root of thread in hole due to worn tap. Minimum flat at root = $1/24\, p$ = 0.00521 in.

¶ The tolerances specified, i.e. (max. pitch diam. − min. pitch diam.), are cumulative, and include variations in lead and angle.

*(Continued from p. 9-08)*

Limiting dimensions for 8-pitch and 16-pitch thread series are given in Tables 10 and 11.

**Class 4 Fit.** Screws and holes threaded to Class 4 specifications are intended to meet unusual requirements, more exacting than those for which Class 3 is intended. It is a selective fit if initial assembly by hand is required and is not as yet (1935) adaptable to quantity production. There is an actual interference between a maximum screw and a minimum hole inasmuch as the pitch diameter of the maximum screw is greater than the basic value by a definite allowance, and the pitch diameter of the minimum hole is basic. With a minimum screw and maximum hole a very slight amount of play is present when the total Class 4 pitch diameter tolerance has been applied to both parts. In Class 4 fits, the minimum nut is basic. The pitch diameter of the minimum screw is above basic by the amount of the interference specified in Table 3. The tolerance on the nut is plus and on the screw is minus. Pitch diameter tolerances for a screw or nut of a given pitch in the coarse- and fine-thread series are specified in Table 4. Limiting dimensions are given in Tables 8 and 9.

* Pitch $p = 0.06250$ in.; basic depth of thread $h = 0.04059$ in. † Basic diameter.

‡ Dimensions are figured to intersection of worn tool arc with center line through crest and root; minimum flat at root = $1/8\ p = 0.00781$ in.

§ Dimensions given are allowable only with tap having theoretically sharp corners. Threaded hole must not reject correct basic 'Go' gage through interference between gage and rounded root of thread in hole due to worn tap. Minimum flat at root = $1/24\ p = 0.00260$ in.

¶ The tolerances specified, i.e. (max. pitch diam. − min. pitch diam.), are cumulative, and include variations in lead and angle.

**All Classes.**—Tolerances for pitch diameter as specified in Table 4 are cumulative and include all variations of lead and angle. The full tolerance on pitch diameter, therefore, is not available unless lead and angle of the thread are perfect. Variations in lead (per length of thread engaged) and in angle, respectively, can each be compensated by half the tolerance on pitch diameter shown. If lead and angle variations both exist to the amount tabulated, the pitch diameter must be reduced by the full tolerance or the thread will not enter a basic nut or gage, nor is the full tolerance available unless the gage is perfect. If no lead variation existed, the angle variation could be twice that given and *vice versa*. These extreme conditions, however, are not desirable.

Specified tolerances are based on the length of engagement not to exceed the nominal or major diameter of the screw, except in the 8-pitch, 12-pitch and 16-pitch thread series. In the 8-pitch series, they are based on a length of engagement of 1 × major diameter for sizes from 1 to 3 in. inclusive, and a length of engagement of 3 in. for sizes over 3 in. In the 12-pitch and 16-pitch series, they are based on a length of engagement of six threads. Where greater lengths of engagement are required, a corresponding increase in the accuracy of lead and thread form is necessary. This may be obtained by the use of more accurate threading tools and longer "Go" gages.

Crest clearances allowed will permit rounded root forms in both nut and screw which may be formed by tools perfectly rounded, or rounded as the result of wear. The maximum minor diameter is that which would result from using a threading tool, set at the maximum pitch diameter, whose point has been worn or ground back from the basic outline by an amount equal to 1/18 of the basic depth of engagement, or 0.03608 × pitch.

**THE DARDELET THREAD** was designed primarily as a thread on which the nut would be self locking. Fig. 6 is a section of the thread through the nut and bolt. The thread is similar in form to the Acme thread (see Fig. 2), the sides being inclined at an angle of 14 1/2 deg. The bases of the several threads on the bolt are joined by a surface inclined at 6 deg. to the axis of the bolt. The crests of the nut thread are parallel to the surfaces joining the bases of the bolt threads. The distance between the successive corresponding thread faces is about 1 3/4 times the thickness of the thread at the mean thread diameter. A space exists between the threads of the nut and the bolt when the two are assembled together. These relations are shown in Fig. 6.

**Table 12.—S.A.E. Standard Screw Threads, Extra Fine Series**

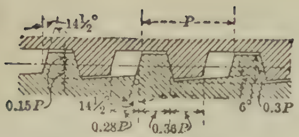

FIG. 6. Dardelet Thread

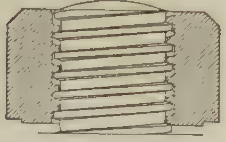

FIG. 7. Dardelet Thread, Unlocked

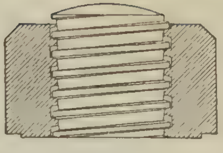

FIG. 8. Dardelet Thread, Locked

The action of the Dardelet thread as a locking device is shown in Figs. 7 and 8. In the unlocked position, the lower faces of the nut threads rest on the upper faces of the bolt threads as shown in Fig. 7. When the nut is screwed down into contact with the work, the bolt is drawn up until the lower faces of the bolt threads bear on the upper faces of the nut threads, as shown in Fig. 8. Prior to this contact, the inclined crests of the nut threads have come into contact with the tapered root section of the bolt thread. As the rotation of the nut is continued the inclined crests are compressed against the tapered roots of the thread with continually increasing pressure, until the load finally is taken by the sides of the thread coming in contact. Since vibration varies with the stress in the bolt, it affects only the load on the sides of the threads. It has no influence on the binding stress between the tapered root-sections and inclined crests. This form of thread, therefore, forms a positive threadlock.

Dardelet threads are made in a standard series, and in a fine-thread series which correspond in major diameters and pitch with the American National Standard thread. Elements of the Dardelet threads are given in Table 13, and limiting dimensions in Tables 14 and 15. Dimensions correspond to American National Standard Nuts.

Dardelet threads can be made by any of the processes commonly used for forming threads in machine tools. They also can be cut with thread chasers or taps, or they may be cold or hot rolled. Tests made at Columbia University and the U. S. Bureau of Standards show them to be stronger than American National Standard threads. See p. 9–43. Complete data for the forming of these threads, together with design data, records of tests, heat treatment, etc., are given in a 200-page handbook issued by the Dardelet Threadlock Corp., New York.

**WHITWORTH STANDARD THREADS.**—In the Whitworth or English system the angle of the thread is 55 deg. The point and the root of the thread are rounded to a radius of $r = 0.1373 \times$ pitch. The depth of the thread is $d = 0.6403 \times$ pitch. See Fig. 9 and Table 16.

**FRENCH AND INTERNATIONAL STANDARD THREADS.**—The formulas for French, International, and American standard threads are all the same, the only difference being that the pitches of the first two are stated in metric measure and in application give somewhat finer values for corresponding diameters, than does the latter system. While the clearance at the bottom of the thread shall not exceed $^1/_{16}$ of the height of the original triangle according to both the International and the French standards, the former leaves the shape of the bottom of the thread to the manufacturer, whereas the French standard makes the bottom of the thread flat. See Table 17.

**BRITISH ASSOCIATION STANDARD THREAD.**—The angle between the threads is 47 $^1/_2$ deg. The depth of the thread $d = 0.6 \times$ pitch. The tops and bottoms of the threads are rounded with a radius of $r = {^2/_{11}} \times p$. See Fig. 10 and Table 18.

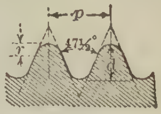

Fig. 10. British Association Thread

**THREADLOCKS.**—The most common form of threadlock is a jam nut, screwed tightly against the first nut. This is not a particularly satisfactory lock, as the two nuts frequently act as a single nut and both are loosened by vibration. More positive means of locking are shown in Fig. 11. The Dardelet thread (see p. 9–14) is practically vibration proof.

Spring or lock washers are quite commonly used to prevent nuts from loosening, and

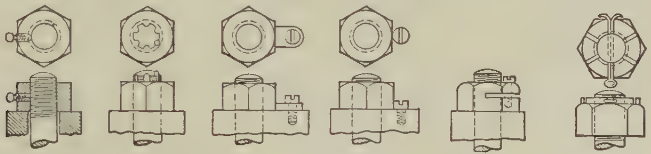

Fig. 11. Methods of Locking Nuts

for ordinary service are quite satisfactory. The S.A.E. standard lock washer is shown in Fig. 12. Dimensions are given in Table 20. Another form of lock washer that has proved successful is that shown in Fig. 13, made by the Shakeproof Lock Washer Co., Chicago. The teeth on the internal or external circumference are twisted out of the plane of the washer. The sharp edges of the teeth bite into both the surface of the nut and of the work and resist any tendency of the nut to unscrew under the influence of vibration. Dimensions of stock sizes are given in Table 21. These washers are made in steel and bronze, and also are made with both internal and external teeth and with countersunk teeth for use with countersunk-head screws.

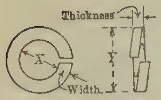

Fig. 12. S.A.E. Standard Lock Washer

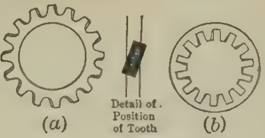

Fig. 13. Shakeproof Lock Washer

**TAPS.**—Tables 22 and 23 show the form and dimensions of machine screw taps, hand taps, tapper taps and nut taps with both cut and ground thread. Cut thread taps should produce holes within Class 2 screw thread tolerances. Ground taps should produce holes within Class 3 tolerances. See Table 4. The form of thread and the dimensions of thread are given in Table 3. The tolerances for the various classes and sizes of taps are given in Table 24.

## 3. BOLTS, NUTS AND SCREWS

The distinction between bolts, studs, cap-screws, tap-bolts and machine-screws is shown in Fig. 14. The length includes the heads of flat-head screws, stove-bolts and stove-rods. It excludes the heads of bolts, cap-screws, tap-bolts, round- and fillister-head machine screws, round-head stove-bolts and stove-rods, and about one-half the head of round-head wood screws.

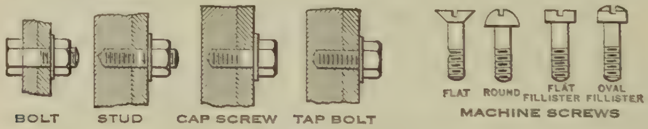

FIG. 14. Forms of Screw Fastenings

If it can be avoided, a hole in cast-iron never should be tapped, as the iron is weak and brittle, and tends to crumble. When it is necessary to tap cast-iron, studs should be used if the attached parts require frequent removal. The cast-iron thread would soon wear if cap-screws were used, whereas the stud is put in once for all.

**BOLTS.**—Standard bolt heads are classed as unfinished, *i.e.*, not machined on any surface, semi-finished, *i.e.*, machined under the head only, and finished, *i.e.*, machined on all surfaces. Bolts and nuts are further classified as: Regular series bolts and nuts, which are intended for general use; heavy bolts and heavy nuts, which are used where greater bearing surface is necessary, or where a large clearance between the bolt and the hole, or where a greater wrench bearing surface is essential; light series nuts, used where extreme saving in weight and material is desirable.

**Regular Bolt Heads and Nuts.**—The dimensions of American Standard regular bolt heads and nuts are given in Table 26. The width across the flats of all bolt heads is $1\ 1/2\ D$, adjusted to sixteenths of an inch, where $D$ = diameter of bolt, except for the sizes of 1/4 to 5/8 in. inclusive, of finished bolt heads. For these bolts, the width across flats is $(1\ 1/2\ D + 1/16)$, adjusted to sixteenths. The tolerance for the width across flats is as follows: Unfinished and semi-finished, minus $0.050\ D$ from basic; finished bolt heads minus $(0.015\ D + 0.006)$ from basic. The minimum width across rounded corners of square bolt heads is: Unfinished and semi-finished square bolt heads, 1.373 × minimum width across flats; minimum width across rounded corners of unfinished, semi-finished, and finished hexagon bolt heads is 1.14 × minimum width across flats. The nominal height of head is the distance from the top to the bearing surface. For unfinished bolts it is $2/3\ D$, adjusted to fractions, and for finished bolt heads it is ${}^3/_4\,D$. For semi-finished bolt heads, the nominal height is as follows:

| | | | | |
|---|---|---|---|---|
| Size, in. . . . . . . . . . . . . | ${}^1/_4$ to ${}^7/_{16}$ | ${}^1/_2$ to ${}^7/_8$ | 1 to 1 ${}^7/_8$ | 2 to 3 |
| Height. . . . . . . . . . . . . | $({}^2/_3\,D - {}^1/_{64})$ | $({}^2/_3\,D - {}^1/_{32})$ | $({}^2/_3\,D - {}^1/_{16})$ | $({}^2/_3\,D - {}^1/_8)$ |

These values all are adjusted to the nearest ${}^1/_{64}$ in., with a tolerance of $\pm(0.016\,D + 0.012)$ from nominal. This also is the tolerance for unfinished bolt heads. For finished bolt heads it is $\pm(0.015\,D + 0.003)$. The tops of all bolt heads are flat and chamfered at an angle to the top surface of 25 deg. for square, and 30 deg. for hexagon. The diameter of the top flat circle is the maximum width across flat. The maximum radius under the head for all classes of bolts and heads is as follows:

| | | | | |
|---|---|---|---|---|
| Size of bolt, in. . . . . . . . . . . . . . . . . . . . . . . | ${}^1/_4$ to ${}^1/_2$ | ${}^9/_{16}$ to 1 | 1 ${}^1/_8$ to 2 | 2 ${}^1/_4$ to 3 |
| Max. radius, in. . . . . . . . . . . . . . . . . . . . . . . | ${}^1/_{32}$ | ${}^1/_{16}$ | ${}^1/_8$ | ${}^3/_{16}$ |

**Heavy Bolt Heads.**—Table 26 gives the dimensions of American Standard heavy bolt heads. The width across flats is $(1\,{}^1/_2\,D + {}^1/_8)$ adjusted to sixteenths. The tolerance for width across flats and for minimum width of rounded corners is the same as for regular bolt heads. Nominal height of head, and tolerances, are as follows: Unfinished bolt heads, height, $({}^3/_4\,D + {}^1/_{16})$, tolerance, minus $(0.016\,D + 0.012)$ from nominal; finished bolt

heads, height, $(D - 1/16)$, tolerance, minus $(0.015\,D + 0.003)$ from nominal. Nominal heights and tolerances of semi-finished bolts are as follows:

| | | | |
|---|---|---|---|
| Size, in. | 1/2 to 7/8 | 1 to 1 7/8 | 2 to 3 |
| Height | $(3/4\,D + 1/32)$ | $3/4\,D$ | $(3/4\,D - 1/16)$ |

Tolerance, all sizes, $\pm(0.016\,D + 0.012)$ from nominal.

Chamfer of top of head and radius under head are the same as for regular bolt heads.

### Table 27.—Length of Thread on Bolts

**Length of Thread on Bolts.**—Table 27 from *Machinery's Handbook* gives the length of thread on bolts up to $1\,^1/_4$ in. diameter and up to 20 in. long. For bolts exceeding these dimensions, the length of thread is made equal to 3 times the bolt diameter.

**NUTS.**—American Standard nuts are classified as regular and jam nuts, and are further classified as unfinished, semi-finished and finished nuts. Unfinished nuts are threaded but not machined on any surface. Semi-finished nuts are threaded and machined on the bearing surface only. Finished nuts are threaded and machined on all surfaces. The width across the flats of all types of nuts is $1\,^1/_2\,D$, except for sizes $^1/_4$ to $^5/_8$ in., where width across flats equals $1\,^1/_2\,D + {}^1/_{16}$, with a tolerance of minus $0.050\,D$ from basic for unfinished and semi-finished nuts, and of minus $(0.015\,D + 0.006)$ from basic for finished nuts. Minimum width across rounded corners is the same as for bolt heads. The nominal thickness is the overall distance from the top to the bearing surface and is equal to $^7/_8\,D$ for unfinished and finished nuts. For semi-finished nuts it is as follows:

| Size, in. . . . . . . . . . | $^1/_4$ to $^7/_{16}$ | $^1/_2$ to $1\,^1/_8$ | $1\,^1/_4$ to $2\,^1/_4$ | $2\,^1/_2$ to 3 |
|---|---|---|---|---|
| Thickness. . . . . . . . | $(^1/_2\,D + {}^1/_{64})$ | $(^1/_2\,D + {}^3/_{64})$ | $(^1/_2\,D + {}^1/_{16})$ | $(^1/_2\,D + {}^5/_{32})$ |

**Table 29.—Dimensions of American Standard Regular and Heavy Nuts**

A.S.A., B18.2—1933. All dimensions in inches

| Diam., $D$ | Unfinished and Semi-finished Square and Hexagon | | | | | | | | Finished Hexagon | | | | |

The tolerance for the thickness of unfinished and semi-finished nuts is $\pm(0.016\,D + 0.012)$ from nominal. For finished nuts it is $\pm(0.015\,D + 0.003)$ from nominal. The top of square and hexagon nuts are washer crowned or flat and chamfered, the chamfer being the same as for bolt heads. Bearing surface of semi-finished nuts is machined plain with chamfered corners, or machined to a washer face 1/64 in. thick and of diameter equal to maximum width across flats; for finished nuts it is a washer face of the same dimensions as a semi-finished nut. Table 29 gives dimensions of regular and heavy nuts.

**Jam Nuts.**—Jam nuts are similar in all respects to the regular nuts, except thickness. The thicknesses of the several classes of jam nuts are as follows:

| Size, Regular | 1/4 to 7/16 | 1/2 to 1 1/8 | 1 1/4 to 2 | 2 1/2 to 3 |
|---|---|---|---|---|
| Unfinished | $(1/2\,D + 1/32)$ | $(1/2\,D + 1/16)$ | $(1/2\,D + 1/8)$ | $(1/2\,D + 1/4)$ |
| Semi-finished | $(1/2\,D + 3/64)$ | $(1/2\,D + 3/64)$ | $(1/2\,D + 1/16)$ | $(1/2\,D + 5/16)$ |
| Finished | $(1/2\,D + 1/32)$ | $(1/2\,D + 1/16)$ | $(1/2\,D + 1/8)$ | $(1/2\,D + 1/4)$ |

| Size, Heavy | 1/2 to 1 1/8 | 1 1/4 to 2 1/4 | 2 1/2 to 4 |
|---|---|---|---|
| Unfinished | $(1/2\,D + 1/16)$ | $(1/2\,D + 1/8)$ | $(1/2\,D + 1/4)$ |
| Semi-finished | $(1/2\,D + 3/64)$ | $(1/2\,D + 1/16)$ | $(1/2\,D + 5/16)$ |
| Finished | $(1/2\,D + 1/16)$ | $(1/2\,D + 1/8)$ | $(1/2\,D + 1/4)$ |

The tops and bottoms of double crown finished jam nuts are flat, and chamfered the same as finished regular nuts. Dimensions of jam nuts are given in Table 30.

**Light Nuts.**—Table 31 gives the proportions of American Standard light nuts and American Standard light castle nuts. The tolerance for width across flats is minus $(0.015\,D + 0.006)$ from basic. Minimum width across corners of hexagon is $(1.14 \times$ minimum width across flats$)$. Nominal thickness of a light nut is distance from top to bearing surface, and equals $^{7}/_{8}\,D$ adjusted to fractions. Tolerance for thickness is $\pm(0.015\,D + 0.003)$ from nominal. On light castle nuts the height of the top circle above flats is not less than the depth of the slot. On light nuts, the finished top is flat and chamfered at an angle of 30 deg. with top surface; diameter of top circle is minimum width across flats, with a tolerance of ± 15%. The bearing surface of both light nuts and light castle nuts is washer-faced; thickness of washer is $^{1}/_{64}$ in., and diameter is the maximum width across flats with a tolerance of ± 5%. The bearing surface must be at right angles to the axis of the threaded hole within a tolerance of 2 deg. for 1-in. nuts or smaller, and 1 deg. for nuts of over 1-in. size. Both light nuts and light castle nuts usually are supplied with fine threads. Semi-finished nuts are threaded, and are machined only on bearing surfaces.

**Machine-screw and Stove-bolt Nuts.**—Dimensions are given in Table 32. The width across flats for sizes $^{1}/_{4}$ to $^{3}/_{8}$ in. equals $(1\,^{1}/_{2}\,D + {}^{1}/_{16})$ adjusted to sixteenths. Tops and bottoms of square nuts and bottoms of hexagon nuts are flat. In all other respects except thickness the nuts correspond to American Standard semi-finished regular nuts.

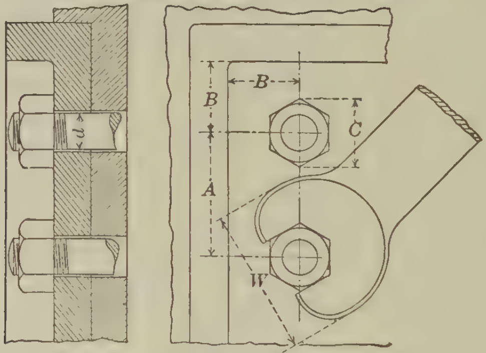

FIG. 15. Wrench Clearance Dimensions

**BOLT SPACING FOR WRENCH CLEARANCE.**—The following formulas are given in *Machinery's Handbook* for the minimum spacing between bolts, and between bolts and adjacent projections, to afford sufficient clearance for the usual form of open-end wrench.

$$A = 1/2\,W + 1/2\,C + 1/2\,d; \quad B = 0.48\,W.$$

See Fig. 15 for notation. All dimensions are in inches. A value of $W = (3.5\,d + 1/8)$ will cover the most of the commercial open-end wrenches. See Tables 29 to 32 for values of $C$.

**WRENCH HEAD OPENINGS** for standard bolts and nuts are given in Table 33. The minimum wrench openings provide a positive clearance between maximum nut and minimum wrench opening. Tolerances on wrench openings are plus only.

**STOVE BOLTS** are made with both round and countersink heads, in diameters of 1/8, 5/32, 3/16, 7/32, 1/4, 5/16 and 3/8 in. They may be obtained in practically any length desired, and usually are threaded the entire length. See Fig. 16.

**MACHINE SCREWS.**—Various forms of American Standard machine screws are shown in Fig. 20. The unthreaded body diameter will have approximately the same tolerances as the pitch diameter of American Standard screw threads, Class 2 free fit, for corresponding number of threads per inch. See p. 9–07. The formulas for determining the various dimensions of the several types of screws are as follows: Head diameter, flat head and oval head, $A_{\max} = (2.040\,D - 0.003)$; $A_{\min} = (1.960\,D - 0.013)$; round head, $A_{\max} = 1.887\,D$, $A_{\min} = (1.813\,D - 0.010)$; fillister head, $A_{\max} = (1.670\,D - 0.004)$; $A_{\min} = (1.610\,D - 0.014)$. Height of head, flat head and oval head, $H_{\max} = (0.619\,D - 0.002)$; $H_{\min} = (0.552\,D - 0.007)$; round head, $H_{\max} = (0.636\,D + 0.015)$; $H_{\min} = (0.624\,D + 0.005)$; fillister head, $H_{\max} = (0.660\,D - 0.002)$; $H_{\min} = (0.600\,D - 0.007)$. Width of slot, all types, $J_{\max} = (0.182\,D + 0.020)$; $J_{\min} = (0.164\,D + 0.010)$. Depth of slot, flat head, $T_{\max} = (0.288\,D - 0.002)$; $T_{\min} = (0.192\,D - 0.002)$; round head, $T_{\max} = (0.362\,D + 0.017)$; $T_{\min} = (0.268\,D + 0.013)$; oval head, $T_{\max} = (0.556\,D - 0.003)$; $T_{\min} = (0.460\,D - 0.003)$; fillister head, $T_{\max} = (0.440\,D - 0.001)$; $T_{\min} = (0.374\,D - 0.011)$. Height of oval, fillister head, $F_{\max} = (0.280\,D + 0.004)$; $F_{\min} = (0.220\,D - 0.001)$; oval head, $F_{\max} = (0.304\,D + 0.003)$; $F_{\min} = (0.268\,D - 0.001)$. Countersink angle of both flat and oval head screws is 82 deg. max., 80 deg. min. Table 36 shows the dimension of American Standard machine screw heads. The preferred lengths of the various sizes range as follows, although all lengths are not regularly manufactured for all types of head.

Coarse Thread Series:

| | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|

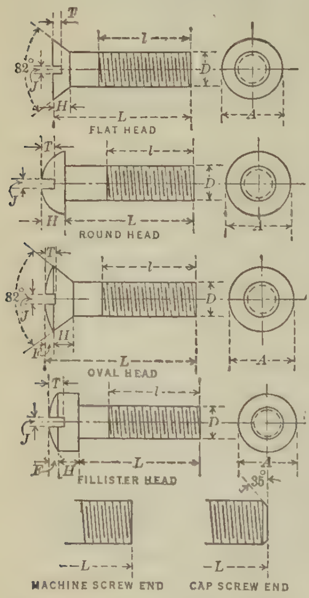

Fig. 20. Machine and Cap Screws

The lengths advance by increments of $^1/_{16}$ in. from $^1/_8$ to $^1/_2$ in.; by increments of $^1/_8$ in. from $^5/_8$ to 1 in.; and by increments of $^1/_4$ in. from 1 $^1/_4$ to 3 in.

SLOTTED HEAD CAP SCREWS are made with flat, button and fillister heads. The unthreaded body diameter has the same tolerances as the major thread diameter of American Standard screw threads, Class 2 free fit, for corresponding number of threads. See p. 9-07. The formulas for the various dimensions of the several types are as follows: Head diameter, $A_{\text{max}}$, all types, = nominal diam. (no formula). Minimum diameters are: flat head, $A_{\text{min}} = A_{\text{max}} - (0.03\ A_{\text{max}} + 0.008)$; button head, $A_{\text{min}} = A_{\text{max}} - (0.02\ A_{\text{max}} + 0.010)$; fillister head, $A_{\text{min}} = A_{\text{max}} - (0.02\ A_{\text{max}} + 0.004)$. Height of head: Flat head, nominal $H$ is computed from $D_{\text{max}}$ and $A_{\text{max}}$ with 81 deg. angle; button head, $H_{\text{max}} = {}^7/_{16}\ A_{\text{max}}$; $H_{\text{min}} = H_{\text{max}} - (0.03\ A_{\text{max}} + 0.003)$; fillister head, $H_{\text{max}} = {}^2/_3\ D$ to nearest sixty-fourth in.; $H_{\text{min}} = H_{\text{max}} - (0.03\ A_{\text{max}} + 0.004)$. Width of slot, all types, $J_{\text{max}} = S + (0.05\ S + 0.003)$; $J_{\text{min}} = S - (0.05\ S + 0.003)$, where $S$ = approximate cutter width = $(0.160\ D + 0.024)$. Depth of slot: Flat head $T_{\text{max}} = 0.500\ H$ nominal; $T_{\text{min}} = (T_{\text{max}} - 0.08\ D)$; button head, $T_{\text{max}} = {}^2/_3\ H_{\text{min}}$; $T_{\text{min}} = (T_{\text{max}} - 0.08\ D)$; fillister head, $T_{\text{max}} = (0.50\ F_{\text{min}} + H_{\text{min}})$; $T_{\text{min}} = (T_{\text{max}} - 0.08\ D)$. Height of oval, fillister head, $F_{\text{max}} = (0.110\ A_{\text{max}} + 0.002)$; $F_{\text{min}} = 0.100\ A_{\text{max}}$.

The length of a cap screw is measured from the largest diameter of bearing surface of the head to the extreme point on a line parallel to the axis of the screw. The difference between consecutive lengths of screws is as follows: Screws $^1/_4$ to 1 in., $^1/_8$ in.; 1 to 4 in., $^1/_4$ in.; 4 to 6 in., $^1/_2$ in. The threads are coarse pitch and the length of thread $l = 2\ D + {}^1/_4$. Dimensions of American Standard cap screws are given in Table 37.

### Table 37.—Dimensions of American Standard Cap Screws

| 1 1/2 | ......... | ......... | ......... | ......... | ......... | 1.5000 | 1.464 | 1.159 | 1.091 |

**Hexagon-head Cap Screws** are machined on all surfaces. The width across the flat of 1/4- to 7/16-in. screws is $(D + 3/16)$; for 1/2- to 7/8-in. screws, $(D + 1/4)$; for 1-in. screws, $(D + 5/16)$; for 1 1/8 in. screws $(D + 3/8)$; for 1 1/4 in. screws, $(D + 7/16)$. The tolerance for width across flat is minus $(0.015\,D + 0.003)$ from nominal. The tops and bearing faces correspond to American Standard regular finished hexagon bolt heads. Dimensions are given in Table 38.

**Socket-head Cap Screws** are shown in Fig. 21, and dimensions are given in Table 39. The body diameter $D$ refers to the unthreaded portion and is the nominal diameter of the screw. The thread may be either American National Standard coarse thread or fine thread. The heads are flat and chamfered at an angle $E$ of 30 deg. ± 2 deg. The socket depth is made as great as practicable. The length of thread $l$ is measured from the extreme point to the last usable thread and is as follows: For American National coarse thread, $l = 2\,D + 1/2$ in., where $l > 1/2\,L$; $l = 1/2\,L$ where $l > 2\,D + 1/2$ in. For American National fine thread, $l = 1\,1/2\,D + 1/2$ in. where $l > 3/8\,L$; $l = 3/8\,L$ where $l > 1\,1/2\,D + 1/2$ in.

The point chamfer $Z$ is an angle of $35°, +5°, -0°$.

* Minimum diameter is 0.001 in. less than maximum diameter for sizes No. 5 to 8 inclusive; 0.002 in. less for sizes No. 10 to 9/16 in. inclusive; 0.003 in. less for sizes 5/8 to 7/8 in. inclusive; 0.004 in. less for sizes 1 to 2 in. inclusive.

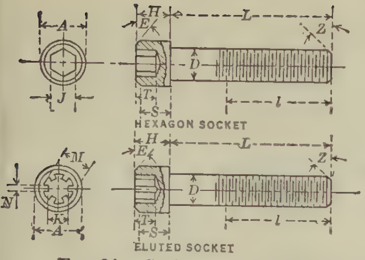

Fig. 21. Socket-head Cap Screw

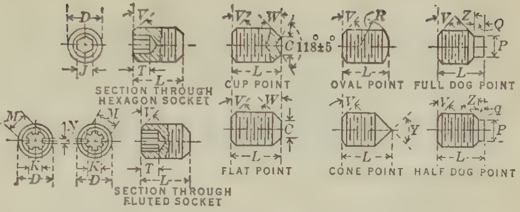

Fig. 22. Socket Set-screw

The length under the head $L$ is measured on a line parallel to the axis, from the plane of the bearing surface to the plane of the flat of the point. The increments of length are as follows:

| | | | |
|---|---|---|---|
| Screw length, in. | 1/4 to 1 | 1 to 4 | 4 to 6 |
| Increment, in. | 1/8 | 1/4 | 1/2 |

**SET-SCREWS** are made both with square heads or with sockets into which a wrench may be inserted for tightening.

**Square Head Set-screws.**—The width across the flats is equal to the diameter $D$ of screw, with a tolerance of minus $(0.020D + 0.006)$ from basic, except for 1/4- and 5/16-in. screws. Tolerances for these sizes are given in Table 38. The minimum width across rounded corners is 1.373 × minimum width across flats. The height of head is $3/4\,D$ with a tolerance of $\pm(0.020\,D + 0.004)$ from nominal. The maximum width of the neck under the head, for sizes of 3/8 in. and larger, is twice the pitch of the thread. The sizes under 3/8 in. are not necked, but are beveled not more than 40 deg. under the head. The radius of the crown of the head is 2 1/2 $D$. The dimensions are given in Table 38.

**Socket Set-screws.**—Socket set screws are made in several forms as shown in Fig. 22. The half-dog-point screw is used where the usable length of thread is less than the nominal diameter. Threads conform to the American National Standard thread. See p. 9–04. The sockets may be either hexagonal or fluted. Dimensions of both types are given in Table 40. The socket depth $T$ is made as great as practicable, but definite values are not specified. The socket end of the screw is flat and chamfered at an angle $V = 35°, +5°, -0°$. The chamfer $W$ on the point end of cup-point screws is $45°, +5°, -0°$. The chamfer $Z$ of dog-point screws is $35° + 5°, -0°$. Dimensions of socket set screws are given in Table 40. The length of socket screws increases by the following increments:

| | | | | |
|---|---|---|---|---|
| Screw length, in. | 1/4 to 5/8 | 5/8 to 1 | 1 to 4 | 4 to 6 |
| Increment, in. | 1/16 | 1/8 | 1/4 | 1/2 |

**SELF-TAPPING SCREWS** are screws that may be driven into an untapped hole, forming the thread in the hole as they are driven. One form, with a sharp, hardened, widely spaced V-thread, is used to join sheet-metal parts or fasten sheet metal to aluminum, bakelite or other relatively soft substances. Another form, shown in Fig. 24 is tapered for a short distance from the end. A short slot cut in the tapered section forms, in effect, a single-flute tap which cuts a thread in the material as the screw is screwed into it. These screws can be used with the softer materials and also with steel, cast iron, brass and bronze. Sizes of screws and sizes of holes for them are given in Table 42.

**LAG SCREWS AND COACH SCREWS.**—Lag screws and coach screws are made with a cone point or a gimlet point, and have a wood-screw thread. Lag screws have a square, and coach screws a hexagon head. See Fig. 25 and Table 43.

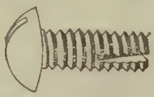

Fig. 24. Self-tapping Screw

Fig. 25. Lag Screw

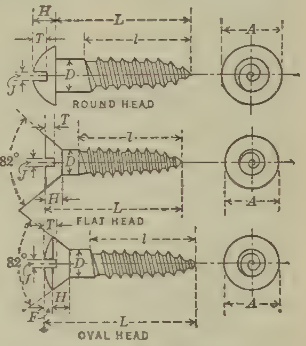

Fig. 26. Wood Screws

**WOOD SCREWS.**—Wood screws are made with round, flat, and oval heads as shown in Fig. 26. Dimensions of the various forms are given in Table 44. The various dimensions are determined by the following formulas: Head diameter, round head, $A_{max} = 1.887\,D$; $A_{min} = (1.813\,D - 0.010)$; flat head and oval head, $A_{max} = (2.04\,D - 0.003)$; $A_{min} = (1.96\,D - 0.013)$. Height of head, round head, $H_{max} = (0.636\,D + 0.015)$; $H_{min} = (0.624\,D + 0.005)$; flat and oval head, $H_{max} = (0.619\,D - 0.002)$; $H_{min} =$

oval head, $T_{\max} = (0.556\,D - 0.003)$; $T_{\min} = (0.460\,D - 0.003)$. Height of oval, oval head screws, $F_{\max} = (0.304\,D + 0.003)$; $F_{\min} = (0.268\,D - 0.001)$. Countersink angle, flat and oval head screws, max., 82 deg., min., 80 deg. The shape of the head of round head screws is semi-elliptical.

Fig. 27. Drive Screw

**DRIVE SCREWS.** (American Screw Co.)—Drive screws, Fig. 27, are driven in with a hammer. They have greater holding power than nails and can be withdrawn with an ordinary screwdriver. They are made with flat heads only, from 1/2 to 3 1/2 in. long, and from No. 4 to No. 20 diam.

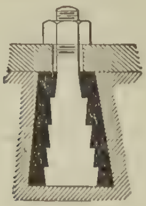

Fig. 28. Rag Bolt

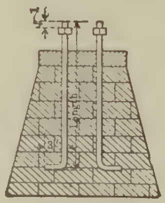

Fig. 29. Built-in Anchor Bolt

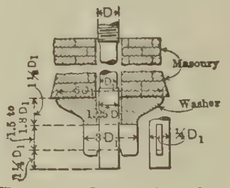

Fig. 30. Cottered Anchor Bolt

**FOUNDATION BOLTS** used for holding machine frames, engine beds, roof trusses, etc., to concrete or masonry may be divided into two classes, *viz.*, those embedded in the masonry and those passing through it. The rag bolt having a tapered shank with jagged edges is shown in Fig. 28. A hole wider at the bottom than at the top is cut in the masonry; the bolt is placed in position and molten lead is poured between the masonry and bolt. A built-in anchor bolt is shown in Fig. 29. A form of cottered bolt passing entirely through the masonry, with a washer and cotter at its lower end is shown in Fig. 30. The proportions are taken from Marshall (Machine Design and Drawing).

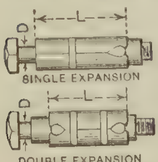

Fig. 31. Expansion Bolt

**EXPANSION BOLTS** are used for attaching wood or iron parts to masonry. With the Star expansion bolt, Fig. 31, a hole is drilled in the masonry of such size that the expansion nut or shield will fit it closely. When the bolt is screwed up the nut expands and binds firmly in the masonry. In most forms, however, the body of the bolt is divided and when the head of the bolt is turned, the sections forming the body of the bolt are

* 1 1/4 in. for plain anchorage.

forced outward, binding in the masonry. The diameter of the expansion bolt is the size of the bolt itself and not the diameter of the shield or expansion member. The length of the bolt is found by adding together the thickness of material to be fastened and the length of the shield. In using expansion bolts, a hole of the size shown in Table 46 is drilled, into which the shield is inserted. The bolt is run through the object to be fastened into the shield and tightened.

The Cinch anchor made by the National Lead Co., New York, shown in Fig. 32, can be used wherever an expansion bolt can be applied. It consists of the conical malleable iron wedges $A$, and the lead composition sleeves $B$. The plain anchor is assembled on a bolt, which is inserted in the hole in the structure. It is then calked in by a pipe or sleeve placed over the bolt. When the bolt is drawn up by the nut the wedges are forced into the lead sleeves, expanding them into the hole, making an exceptionally strong anchorage. In the threaded anchorage, the innermost sleeve has a thread, forming a nut into which a standard bolt can be screwed. It is calked in place by means of a dummy bolt which is removed after calking is finished. With the plain anchorage the bolt cannot be removed, whereas it can be removed from the threaded anchorage. These anchorages are made with two units and three units. Dimensions are given in Table 47.

Two-Unit Threaded Anchorage

Two-Unit Threaded Anchor Installed

Fig. 32. Cinch Anchor

**THE HOOK BOLT** is used to connect pieces where it is impossible or impracticable to put a bolt hole through one of the pieces to be connected. Hook bolts are often used to attach shaft hangers to the flanges of joists and girders. Spooner (Machine Design, Construction and Drawing) gives the proportions shown in Fig. 33.

§ A tolerance of −0.031 in. is allowed on sizes 1/4 to 3/4 in. inclusive, of −0.047 in. on 1 in. size, and of −0.063 in. on 1 1/4 and 1 1/2 in. size.

¶ A tolerance of −0.010 in. is allowed on sizes 1/4 to 5/8 in. inclusive, and of −0.015 in. on sizes 3/4 to 1 1/4 in.

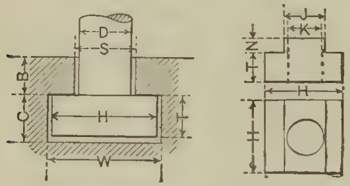

FIG. 34. T-Slot Bolts and Nuts

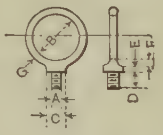

FIG. 35. Lifting Eye Bolt

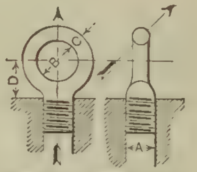

FIG. 36. Special Eye Bolt

**EYE-BOLTS.**—Lifting eye-bolts, Fig. 35, are used for the purpose of lifting machines or machine parts by means of ropes or chains attached to the eyes. The eye-bolt is screwed into a hole near the center of gravity of the piece. Table 49 from *Machinery's* Handbook gives proportions and strength of eye-bolts. Special eye-bolts with increased body, representing the General Electric Co. practice, are given in Fig. 36 and Table 50. These bolts are drop forgings and the arrows indicate the direction of pull to raise the weight. According to the General Electric Co. these sizes should be used in place of the following commercial eye-bolts sizes: 3/4, 1, 1 1/4, 1 1/2 and 2 in., respectively.

**Table 49.—Dimensions of Lifting Eye-bolts**

| 3 1/2 | 3 1/4 | 3 1/2 | 4 | 1 7/8 | 4 | 14,000 | 4800 |

**PATCH BOLTS.**—The function of the patch bolt, Fig. 37, is to fasten patches on the sheets of boilers. They should be used only where it is impossible to use rivets. Stock sizes have 12 threads, of the Am. National Standard, per inch. The length of patch bolts is measured from the point to the large diameter of the head. The stock sizes made by the Pittsburgh Screw & Bolt Co. are: 1/2 in. diameter by 3/4, 7/8 or 1 in. long, and 5/8, 3/4 and 1 in. diameter by 7/8, 1, 1 1/8, 1 1/4 or 1 1/2 in. long.

**STANDARD STUDS.**—The Upson Nut Co., Cleveland, gives the following formulas for the dimensions of standard stud bolts. Let $A$ = diameter of stud; $B$ = length of short thread; $C$ = length of unthreaded portion; $D$ = length of long thread; $E$ = total length of stud, all in inches. Then $B = A + 1/8$; $C = A$; $D = E - (B + C)$.

## 4. STRENGTH OF SCREW FASTENINGS

**STRENGTH OF BOLTS.**—The load that a bolt in simple tension will sustain is

$$P = s\,A \qquad [7]$$

where $P$ = load, lb.; $A$ = minimum cross-sectional area of bolt, sq. in., *i.e.*, area at root of thread; $s$ = stress in bolt, lb. per sq. in. Faires (Design of Machine Elements) gives for the value of $s$ the formula $s = C\sqrt{A}$, from which by substitution in [7]

$$P = C\,A^{3/2} \qquad [8]$$

$C$ is a constant depending on the material used in the bolt. For ordinary steel screw stock of 56,000 lb. per sq. in. ultimate strength $C$ may be taken as 5000 for bolts up to 1 3/4 in. diameter. The value of $C$ for other materials is proportional to the ultimate strength. Thus if $S_a$, $S_s$ = respectively, ultimate strength of an alloy steel and ordinary screw stock, and $C_a$, $C_s$ = respectively, constants for the alloy and ordinary steels, $S_s/S_a = C_s/C_a$. For bolts over 1 3/4 in. diameter, of ordinary steel, the value of $s$ for equation [7] may be taken as 7000, $P$ in this case being the external load. For alloy steel bolts, values of $s$ up to 21,000 lb. may be used.

**Initial Tension,** or stress due to screwing up to the nut may vary over a wide range. Kimball and Barr state that it may be as high as 30,000 $D$, where $D$ is the nominal diameter of the bolt. As the result of experiments on different sizes of bolts tightened by various mechanics, they deduced that the initial load on a bolt, due to tightening, may be taken as $W = 16{,}000\,D$, where $W$ = load, lb. This is equivalent to a tensile stress in the bolt of $p = 27{,}500/D$ lb. per sq. in. The initial tension is indeterminate, as it will vary with the length of wrench used, the effort of the mechanic, and the character of the surfaces in frictional contact.

The action of screwing up also puts torsional stress on the bolt, which in the smaller sizes may exceed the tensile strength. The Kimball and Barr experiments indicated that a 1/2-in. bolt is too small where the nuts are to be screwed up tight. See Working Strength of Bolts, p. 9–44.

**Stress in Bolts Subject to Impact.**—Examples of bolts subject to impact or suddenly applied loads are long bolts acting as tension members in bridges, and bolts in connecting-rod ends. The bolt not only must have sufficient strength to sustain the static load, but have the resistance necessary to absorb the energy of the impacting load. Let $W$ = static value of load, lb.; $A$ = cross-sectional area of bolt, sq. in.; $h$ = height corresponding to velocity with which load is applied, in.; $s$ = unit stress in bolt, lb. per sq. in.; $\Delta$ = deformation produced in bolt by impact load $W\,h$, in. Then

$$s = (2\,W/A)\,\{(h/\Delta) + 1\} \qquad [9]$$

Faires (Design of Machine Elements) gives a modification of formula [9], which is more convenient for checking stress for a given set of conditions when the area remains constant. This formula is

$$s = (W/A) + (W/A)\sqrt{1 + (2\,h\,E\,A/l\,W)} \qquad [10]$$

where $E$ = modulus of elasticity of the bolt material, and $l$ = length of bolt, in.

The strength of a bolt is determined by its cross-sectional area at the root of the thread. Hence the unit stress is higher on this area than in the body of the bolt. The deformation in the threaded portion under shock loads will be greater than in the body of the bolt. If the unit stress in the body of the bolt is made equal to that in the threaded portion, the deformation will be uniform throughout the bolt, and its capacity to resist shock loads will be increased. Fig. 41 shows three methods that may be used. Tie rods for bridges and similar structures are made with upset ends on which the threads are cut, the diameter of the upset being such that the diameter at the root of the thread will be the same as that of the body of the rod.

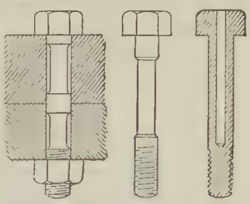

Fig. 41. Bolts for Shock Loads

An investigation to determine the impact and static tensile properties of bolts is reported in U. S. Bureau of Standards Research Paper No. 763, February, 1935. Impact and static tensile tests were made on bolts with nuts having American National Standard coarse threads, American National Standard fine threads, and Dardelet threads. Diameters were 3/8, 1/2, 5/8 and 3/4 in., and materials were heat treated chromium nickel steel, cold rolled Bessemer steel screw stock, Monel metal, a copper-silicon-manganese alloy, and brass. The following is a summary of the conclusions drawn from the tests:

**Impact Tests.**—Except for brass bolts and those which showed stripped threads or brittle failures, the work per unit volume required to rupture bolts was for each material and each type of thread approximately independent of the diameter of the bolt; the stretch in exposed threads was independent of the diameter. The impact work was greater with American National Standard fine threads than with American National Standard coarse threads, and approximately the same for Dardelet threads. Brass bolts with American National Standard fine threads averaged 12% less in impact work than bolts with Dardelet threads. In all cases, the impact work of Dardelet threads was greater than with American National Standard coarse threads.

**Static Tests.**—The static work with American National Standard fine threads was greater than with American National Standard coarse threads and approximately the same as with Dardelet threads. Brass bolts with American National Standard fine threads averaged 26% less static work than bolts with Dardelet threads. The static work in all cases with Dardelet threads was greater than with American National Standard coarse threads. In all cases, the maximum static load with Dardelet threads was approximately equal to the maximum static load with American National Standard fine threads and greater than with American National Standard coarse threads.

For bolts of the same size and having the same threads, the static bolt efficiency, *i.e.*, ratio of maximum static load to product of cross-sectional area of shank × ultimate tensile strength of material, was approximately the same for all classes of material.

**Stress Due to Combined External Load and Initial Tension.**—The maximum value of the combined stress on a bolt is the sum of the initial tension and external loads. This is obtained when the bolt is rigid and the parts which it connects are more or less yielding. The minimum value is either the initial or external load, whichever is greater, obtained with bolts that may yield to a certain extent. In practice, neither condition is attained, the actual stress lying some place between these two extremes. A form of construction in which the combined stress approaches the maximum is shown in Fig. 42, while Fig. 43 shows a type of connection in which the combined stress approaches the minimum value. The judgment of the designer must be exercised to determine the character of stress for which the bolt is to be designed. Kimball and Barr (Elements of Machine Design) quote from *The Locomotive* the following suggestions as a guide:

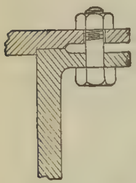

Fig. 42. Rigid Bolt and Yielding Member

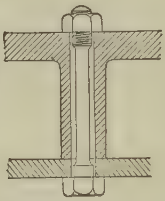

Fig. 43. Rigid Member and Yielding Bolt

When the conditions are such that the nut is apt to be screwed up hard, that is, when the initial load may be safely neglected, design for the external load alone.

When the initial load, due to screwing up, is apt to be considerable:

*a.* If a bolt is manifestly very much more yielding than the connected members, design the bolt simply for the initial load or for the external load, whichever is greater.

*b.* If the probable yield of the bolt is from one-half to once that of the connected members, consider the resultant load as the initial load plus from one-fourth to one-half the external load.

*c.* If the yield of the connected members is probably four or five times that of the bolts, take the resultant load as the initial load plus about three-fourths the external load.

*d.* In case of extreme relative yielding of the connected members, assume the resultant load to be nearly the sum of the initial and external loads.

**WORKING STRENGTH OF BOLTS.**—Forrest E. Cardullo has developed a formula, based on the Kimball and Barr experiments, for the working strength of bolts, which may be expressed as

$$S = s \times \text{working section} \qquad [11]$$

where $S$ = working strength, lb., and $s$ = permissible stress in the bolt, lb. per sq. in. The working section is determined by the formula

$$\text{Working section} = A - (a \times 2D) \qquad [12]$$

where $A$ = area of bolt at the root of the thread; $a$ = area of a $^1/_2$-in. bolt at the root of the thread; $D$ = nominal diameter of bolt. This formula takes account of the fact that the initial stress in a $^1/_2$-in. bolt, produced by screwing up of the nut, frequently equals or exceeds the tensile strength of the material. Table 54 is calculated from this formula on the basis of bolts threaded with American National Standard coarse threads.

**SAFE HOLDING CAPACITY OF SET SCREWS.**—(B. H. D. Pinkney, *Am. Mach.*, Oct. 15, 1914).—The diameter of a set-screw to secure a rotating body of known capacity may be found by formula [13] or [14]:

$$P = T/V \qquad [13]; \qquad P = 63{,}025\, H/nr \qquad [14]$$

where $T$ = torsional moment, in.-lb.; $r$ = radius of shaft, in.; $H$ = horsepower; $n$ = rev. per min., $P$ = resisting pressure, lb., at surface or shaft, which should be equal to, or less than, the safe holding power of a set-screw as follows:

| Size, in....... | $^1/_4$ | $^5/_{16}$ | $^3/_8$ | $^7/_{16}$ | $^1/_2$ | $^9/_{16}$ | $^5/_8$ | $^3/_4$ | $^7/_8$ | 1 | 1 $^1/_8$ | 1 $^1/_4$ |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Capacity, lb.. | 100 | 168 | 256 | 366 | 500 | 658 | 840 | 1280 | 1830 | 2500 | 3288 | 4198 |

The foregoing figures were based on experiments with $^1/_4$-in. and $^1/_2$-in. set-screws, in which it was found that the latter had a capacity of 5 times the former. Set-screws should be securely tightened with a wrench of sufficient leverage. Cup-point and flat-point set-screws are the best to use. The shaft should be provided with a " flat " of width equal to the diameter of the set-screw. The safe holding power of headless set-screws appears to be considerably less than those with heads.

**HOLDING POWER OF NAILS AND SCREWS.—Nails.**—The holding power of nails in wood varies with the specific gravity of the wood, which will vary in any given species. Hence, a considerable variation from published figures may exist in any nailed joint in a given species of wood. Table 55 gives the results of tests on the holding power of nails made by L. J. Markwardt, Senior Engineer, U. S. Forest Products Laboratory, and published in *Am. Lumberman*, July 13, 1929.

**Table 54.—Working Strength of Bolts**

| Diam. of Bolt, in. | Area at Root of Thread, sq. in. | Working Section, sq. in. | Permissible Stress in Bolt, lb. per sq. in. | | | | | | | |

The resistance of nails to transverse loading, when used to fasten two planks together is, according to H. K. Hatt (*Proc.* Ind. Eng. Soc., 1900), $P = cd$, where $P$ = resistance, lb.; $d$ = size of nail, pennyweight; $c$ = a constant whose values are

| | Common Nails | | Finish Nails | | Fence Nails | |
|---|---|---|---|---|---|---|
| | Cut | Wire | Cut | Wire | Cut | Wire |
| Driven in oak | 82 | 70 | 49 | 52 | 100 | .... |
| " " yellow pine | 50 | 48 | 42 | 32 | 90 | 84 |

Joints will slip at about 60% of the loads given by the application of the formula.

**Resistance of Railroad Spikes.**—Values for the resistance of railroad spikes in various species of woods for both axial and lateral pull are given by H. K. Hatt in *Proc.* Am. Ry. Eng. Assoc., 1910, as follows:

| | Red Oak | Shortleaf Pine | Longleaf Pine | Loblolly Pine | Red Gum |
|---|---|---|---|---|---|
| Direct pull, lb. | 7639 | 4359 | 3955 | 3930 | 3883 |
| Lateral pull, lb. | 2026 | 1704 | 1650 | 1633 | 1619 |

The resistance of screw spikes was from 1.7 to 3.8 times greater than that of plain spikes in direct pull, and from 1.2 to 2.4 times greater in lateral pull.

**Resistance of Drift Bolts in Wood.**—Tests at the Watertown Arsenal in 1902 showed the resistance of drift bolts in wood driven parallel to the grain to be about one-half the resistance when driven across the grain. The holding power is in direct proportion to the area of contact and the compressive strength of the wood. There is no difference in the resistance of square drift bolts and round drift bolts of the same diameter. The tests gave the following values for ultimate resistance of drift bolts driven across the grain:

| | 1-in. bolt $^{15}/_{16}$-in. hole | 1-in. bolt $^{13}/_{16}$-in. hole | $^{3}/_{4}$-in. bolt $^{11}/_{16}$-in. hole | $^{3}/_{4}$-in. bolt $^{9}/_{16}$-in. hole | $^{1}/_{2}$-in. bolt $^{7}/_{16}$-in. hole | $^{1}/_{2}$-in. bolt $^{5}/_{16}$-in. hole |
|---|---|---|---|---|---|---|
| Douglas Fir | 2250 | 886 | 800 | 1000 | 374 | 1000 |
| Yellow Pine | 375 | 740 | ... | .... | ... | .... |
| White Oak | 3250 | 1300 | ... | .... | ... | .... |

**Wood Screws.**—Tests made by the U. S. Bureau of Standards to determine the holding power of wood screws in various species of wood (I. J. Fairchild, U. S. Bureau of Stds., *Tech. Bull.* No. 319, July 17, 1926) developed the formula

$$P = wl(120 + 20N) \qquad [15]$$

where $P$ = ultimate resistance to withdrawal, lb.; $l$ = length of screw embedded in wood; $N$ = commercial number representing diameter of screw = $(d - 0.06)\ 0.013$; $w$ = factor depending on the species of wood, values of which are given in Table 56. A wide variation from average values may occur in individual cases, ranging from −25% to +40%. The tests further showed that the diameter of the lead hole in soft wood should be about 70% of the diameter of the root of the thread, and in hard wood about 90%; holding power is not greatly diminished by the use of a lubricant, as soap; in general, long, slender screws are to be preferred, but may fail in tension before the limit of holding power is attained; holding power of screws in end grain is about 75% of holding power across the grain.

**Table 56.—Values of *w* in Fairchild Formula for Holding Power of Wood Screws**

| Wood | $w$ | Wood | $w$ | Wood | $w$ |
|---|---|---|---|---|---|
| Cypress | 1.00 | Maple (Hard) | 3.00 | Pine (White) | 1.00 |
| Douglas Fir | 1.45 | Oak (White) | 2.50 | Poplar (Yellow) | 1.33 |
| Hemlock (Western) | 1.35 | Pine (Georgia) | 2.25 | Spruce | 1.15 |
| Hickory | 4.50 | " (No. Carolina) | 1.90 | Sycamore | 1.75 |

Experiments made in Germany on the holding power of wood screws led to a formula that gives values fairly close to those given by formula [15]. This formula, transformed to U. S. units (D. A. Hampson, *Mech. Engg.*, April, 1929) is

$$H = R(MD + b) \qquad [16]$$

where $H$ = holding power, lb. per inch of screw embedment; $D$ = diameter of screw, in.; $R$, $M$, and $b$ = factors whose values are as follows:

| | Oak | Fir | Larch | Teak | Elm | Ash | Beech |
|---|---|---|---|---|---|---|---|
| $R$ = | 342 | 218 | 316 | 302 | 375 | 297 | 370 |
| $M$ = | 6.6 | 5.7 | 3.6 | 6.7 | 5.5 | 7.4 | 9.1 |
| $b$ = | 1.35 | 1.36 | 1.68 | 1.48 | 1.49 | 1.58 | 1.88 |

**Holding Power of Lag-screws.**—Tests of the holding power of lag-screws in various wood were made by A. J. Cox, at the University of Iowa, 1891, with results as follows:

| Kind of Wood | Size Screw, in. | Size Hole Bored, in. | Length in Tie, in. | Max. Resistance, lb. | No. Tests |
|---|---|---|---|---|---|
| Seasoned white oak.......... | $^5/_8$ | $^1/_2$ | $4\ ^1/_2$ | 8037 | 3 |
| " " " .......... | $^9/_{16}$ | $^7/_{16}$ | 3 | 6480 | 1 |
| " " " .......... | $^1/_2$ | $^3/_8$ | $4\ ^1/_2$ | 8780 | 2 |
| Yellow-pine stick............ | $^5/_8$ | $^1/_2$ | 4 | 3800 | 2 |
| White cedar, unseasoned...... | $^5/_8$ | $^1/_2$ | 4 | 3405 | 2 |

# RIVETS AND RIVETED FASTENINGS

**GENERAL CONSIDERATIONS.**—In making a riveted joint, the head is formed with a set or forming tool, by hand or by hydraulic or pneumatic machines. Machine riveting usually is better than hand work, as the pressure of the machine causes the rivet shank to fill completely the rivet hole. A rivet driven hot shrinks in cooling, pinching the riveted parts and making a firm joint. The cooling also leaves a tensile stress in the rivet, the amount of which cannot be measured. The pinching due to cooling of the rivet causes a frictional resistance between the riveted parts which Stoney found to be about 10,000 lb. per sq. in. of rivet area. American and English practice takes no account of this frictional resistance, but bases design on the tensile and shearing strength of the plates and rivets. Some French and German authorities base design entirely upon the frictional resistance.

## 1. RIVETS

**RIVET HEADS.**—Rivet heads are of many different forms, the particular form being determined by the use of the joint or fastening. Heads of greatest stiffness and strength are used when the rivet is to resist a tensile stress. Countersunk rivets weaken the plate and should be used only where projecting heads are objectionable. The proportions developed by the Hartford Steam Boiler Inspection and Insurance Co., and which have been adopted as standard in the A.S.M.E. Boiler Code, are shown in Fig. 1.

**RIVET HOLES.**—The rivet holes in a plate either may be punched or drilled. The latter is preferred as the action of the punch causes an injurious lateral flow of metal. It is current practice to make holes $^1/_{16}$ in. larger than the cold rivet diameter, except that for rivets not over $^7/_8$ in. diameter a hole of $^1/_{32}$ in. greater diameter than the rivet is preferred. Where work is to be reamed, it is usual to punch the holes $^1/_8$ or $^3/_{16}$ in. less than the finished diameter, and to drill or ream to the proper size after the parts are assembled.

It is good practice to remove the sharp corner at both ends of the reamed holes, so that a fillet will form where the body joins the head in finished rivets. Also, annealing will equalize the internal stresses caused by punching, and thus restore the strength of the plate.

The A.S.M.E. Boiler Code Committee recommends for boiler work that:

Rivet holes, except for attaching stays or angle bars to heads, shall be drilled full size with

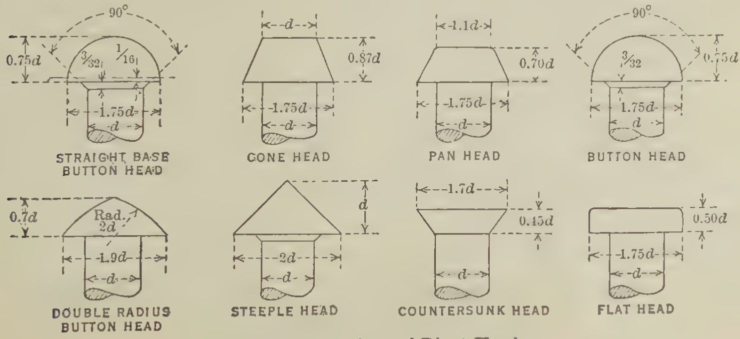

Fig. 1. Proportions of Rivet Heads

plates, butt-straps and heads bolted in position; or they may be punched not to exceed 1/4 in. less than full diameter for plates over 5/16 in. thick, and 1/8 in. less than full diameter for plates not exceeding 5/16 in. thick, and then drilled or reamed to full diameter with plates, butt-straps and heads bolted in position. After drilling rivet holes, the plates and butt-straps shall be separated and the burrs removed.

**ARRANGEMENT OF RIVETS.**—When several rows of rivets are used in lap-joints, the rivets may be arranged as: 1. Chain riveting; 2. Staggered riveting. See Fig. 2. See Figs. 7 to 13 for examples of the use of the two types in boiler work. For allowable shearing and bearing values of rivets in structural work, see Table 25, p. 17–79. For length of rivets for various thicknesses of joint see Table 26, p. 17–80.

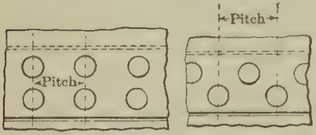

Fig. 2. Chain and Staggered Riveting

**RIVET SPACING.**—Rivet spacing has been the subject of much controversy and experiment. The rivets must be spaced far enough apart to allow proper clearance for use of the set during driving; 3/16 in. is the minimum clearance. However, rivets must not be spaced at such a distance that the fastened parts open between rivets, allowing leakage in a fluid pressure joint, or the accumulation of dirt or water to aggravate rusting in a structural joint. With the usual proportions of riveted joints, a distance from the center of the rivet to the edge of the plate equal to (rivet diameter × 1 1/2), is sufficient to prevent tearing or shearing. The proper rivet spacing for joints in boilers and pressure vessels is given on pages 6–24 to 6–28 of Kent's Mechanical Engineers' Handbook—Power, forming Vol. 2 of this series. See pages 17–14 to 17–19 of this book for standards of the American Institute of Steel Construction for structural work. See also Pitch of Rivets, p. 9–49.

**RIVET MATERIALS.**—It is well known that the strength of rivets is different in single and double shear. Kimball and Barr (Machine Design) recommend the following average values:

| | Shearing Strength, lb. per sq. in. | Crushing Strength, lb. per sq. in. |
|---|---|---|
| Iron rivets, single shear | 40,000 | 60,000 |
| Iron rivets, double shear | 39,000 | 72,000 |
| Steel rivets, single shear | 49,000 | 80,000 |
| Steel rivets, double shear | 42,000 | 100,000 |

The A.S.M.E. Boiler Code prescribes values as follows in computing the ultimate strength of rivets in single shear: Iron rivets, 38,000 lb. per sq. in.; steel rivets, 44,000 lb. per sq. in. For double shear, twice these values are used.

Specifications for steel for rivets are given in A.S.T.M. Specifications, Designation A131–36. See Table 6, p. 2–22. The tests to which the material shall be subjected are given in the notes appended to that table.

**PRESSURE REQUIRED TO DRIVE RIVETS** may be obtained from Fig. 3, which is based on formulas by Wilfred Lewis (*Am. Mach.*, July 13, 1911).

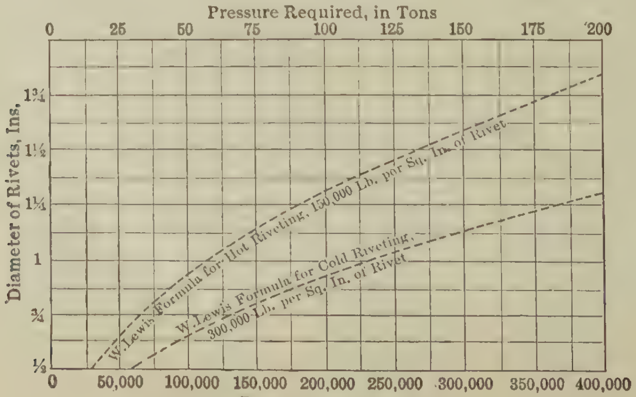

Fig. 3. Pressure Required to Drive Rivets

## 2. RIVETED JOINTS

**FORM OF RIVETED JOINTS FOR MORE THAN TWO PLATES.**—In tanks, boilers, and all pressure vessels requiring tight seams, the problem often is to join three or four plates. Fig. 4 shows method of making such joints.

Fig. 4–A is a junction of three plates, *m*, *n*, and *s*, where both seams are single-riveted lap-joints. The corner of *m* is drawn to an edge and tucked under *s*.

Fig. 4–B is a junction of three plates; one seam is single-riveted and the other is a double-riveted lap-joint. As before, the corner of *m* is drawn down and tucked under *s*.

Fig. 4–C is a junction of three plates with butt-straps; the longitudinal butt-strap is planed down and tucked under the cross butt-strap.

Fig. 4–D is the junction of three plates; the cross seam is a single-riveted lap-joint, and the longitudinal joint is a double-riveted butt-joint with double cover-plates. The upper cover-plate is planed on the end so that it can be tightly calked where it abuts against plate *n*.

Fig. 4–E is a method of joining four plates; both seams are single-riveted lap-joints, *n* and *s*, both being drawn down as shown.

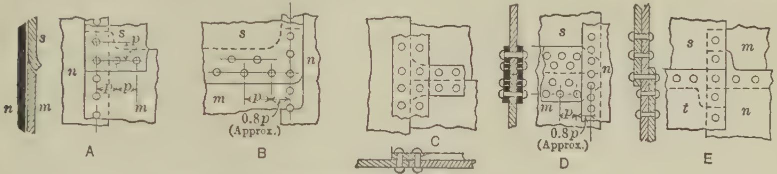

Fig. 4. Riveted Joints for More Than Two Plates

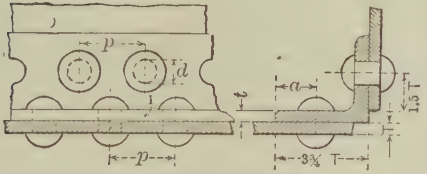

Fig. 5.

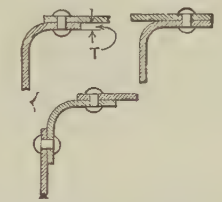

Fig. 6.

Methods of Joining Plates Not in the Same Plane

**Junction of Plates Not in the Same Plane** usually is effected by means of a rolled structural form. Fig. 5 shows an angle used with plates at right angles to each other. If $T$ = thickness of plate and $t$ = mean thickness of angle leg, then $t = T + {}^1/_{16}$ in. The width $w$ of each leg of the angle $= 3.75T$; the diameter $d$ of the rivet $= 2T$ and $a = {}^1/_2\,(w - t)$, where $w$ = width of angle.

Fig. 6 shows methods of connecting plates by flanging the plates themselves instead of using angles. Care should be taken not to use too sharp a radius of curvature and the flange should be annealed after it is bent. The inside radius of the flange must be greater than the thickness of the plate even with the mildest steel. Unwin recommends an inside radius of at least $4T$.

**SIZE AND PITCH OF RIVETS.**—Size and pitch of rivets for different forms of construction, as boiler work and structural work, are determined by the requirements of codes covering such construction. See Kent's Mechanical Engineers' Handbook—Power, pp. 6–25 to 6–28, forming Vol. 2 of this series, for extracts from the A.S.M.E. Boiler Code, and pages 17–14 to 17–19 of this book for riveting for structural work. For other types of construction, the following formulas given by Unwin (Elements of Machine Design) may be used.

Let $d$ = diameter of rivet, in.; $t$ = thickness of plate, in.; $f_b$ = resistance of plate or rivet to crushing, lb. per sq. in. of projected area of rivet; $f_s$ = shearing resistance of rivet, lb. per sq. in.; $f_t$ = tensile strength of plate, lb. per sq. in.; $p$ = pitch of rivets, in.

**Size of Rivet.**—For a rivet in single shear, $d \leqq 1.27\,t(f_b/f_s)$.

For a rivet in double shear, $d \leqq 0.635\,t(f_b/f_s)$.

**Pitch of Rivets.**—Single-riveted joint in single shear, $p = 0.785(d^2/t)(f_s/f_t) + d$.
Single-riveted joint in double shear, $p = 1.57(d^2/t)(f_s/f_t) + d$.
Double-riveted joint in single shear, $p = 0.785(d^2/t)(f_s/f_t) + d$.
Double-riveted joint in double shear, $p = 3.14(d^2/t)(f_s/f_t) + d$.
Triple-riveted joint in single shear, $p = 2.356(d^2/t)(f_s/f_t) + d$.
Triple-riveted joint in double shear, $p = 4.712(d^2/t)(f_s/f_t) + d$.

A joint may fail along a diagonal line between rivet holes unless the net diagonal section is from 30 to 35% greater than the net section along the transverse line between rivet holes. This excess of net section will be obtained with a diagonal pitch of $p_d = 0.667\,p + (d/3)$.

## Strength and Efficiency of Riveted Joints

A riveted joint may fail by shearing the rivets, tearing the plate between the rivets, crushing the rivets or plate, or by a combination of two or more of the above causes. To determine the efficiency or relative strength of a riveted joint, calculate the breaking strength for the different ways in which it may fail. That method of failure which gives the least value determines the actual strength of the joint. This value divided by the strength of the solid plate gives the efficiency of the joint.

The strength and efficiency of various types of riveted joints may be calculated by the following formulas. Tables 1 to 6 show the dimensions and efficiencies of standard boiler joints, as published in the Boiler Book of the Hartford Steam Boiler Inspection and Insurance Co. The dimensions $D$, $E$, and $F$ in these tables may be increased for convenience in riveting, without affecting the efficiency of the joint. They should not be decreased.

**Notation.**—$a$ = diameter of rivet hole, usually $^1/_{16}$ in. greater than rivet, $t$ = thickness of plate, $t_c$ = thickness of cover-plates, $p$ = pitch of inner row of rivets, $P$ = pitch of outer row of rivets, all in inches; and let $f_s$ = shearing strength of rivets; $f_t$ = tensile strength of plate, $f_c$ = crushing strength of rivet or plate, all in lb. per sq. in. Then the resistance for the various joints are as follows:

**Single-riveted Lap-joint**, Fig. 7.—Resistance to shearing one rivet = $(^1/_4\ \pi\ d^2)\ f_s$.
Resistance to tearing plate between rivets = $(p - d)\ t\,f_t$.
Resistance to crushing of rivet or plate = $d\,t\,f_c$.
**Double-riveted Lap-joint**, Fig. 8.—Resistance to shearing two rivets = $2\ (^1/_4\ \pi\ d^2)\ f_s$.
Resistance to tearing between two rivets = $(p - d)\ t\,f_t$.
Resistance to crushing in front of two rivets = $2\,d\,t\,f_c$.
Strength of solid plate = $p\,t\,f_t$.

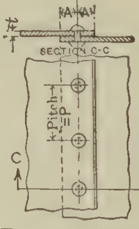

FIG. 8. Single-riveted Lap-joint

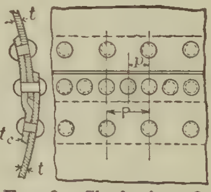

FIG. 9. Single-riveted Lap-joint with Inside Cover Plate

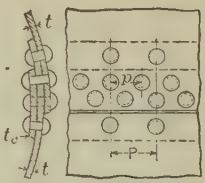

FIG. 10. Double-riveted Lap-joint with Inside Cover Plate

**Table 1.—Dimensions and Efficiency of Double- and Single-riveted Lap-joints for Longitudinal Seams.** (See Figs. 7 and 8)

| Thickness of Plate, in. | Diam. of Rivet Holes, in. | Single-riveted Joints |  |  |  | Double-riveted Joints† |  |  |  |
|---|---|---|---|---|---|---|---|---|---|
|  |  | Efficiency, % | Pitch, in. | $A$, in. | Method of Failure* | Efficiency, % | Pitch, in. | $A$, in. | $B$, in. |
| 1/4 | 11/16 | 60.7 | 1 3/4 | 1 1/16 | T.P. | 69.5 | 2 1/4 | 1 1/16 | 1 3/4 |
| 5/16 | 13/16 | 59.4 | 2 | 1 1/4 | T.P. | 69.1 | 2 5/8 | 1 1/4 | 1 7/8 |
| 3/8 | 15/16 | 58.3 | 2 1/4 | 1 7/16 | T.P. | 68.9 | 3 | 1 7/16 | 2 |
| 7/16 | 1 1/16 | 57.5 | 2 1/2 | 1 5/8 | T.P. | 68.5 | 3 3/8 | 1 5/8 | 2 1/8 |
| 1/2 | 1 1/16 | 56.7 | 2 1/2 | 1 5/8 | S.R. | 68.5 | 3 3/8 | 1 5/8 | 2 1/8 |

* T.P. = failure by tearing plate in net section between rivet holes; S.R. = failure by shearing of rivets.

† All joints fail by tearing net section of plate between rivet holes.

**Single-riveted Lap-joint, Inside Cover-plate,** Fig. 9.—Resistance to tearing between outer row of rivets = $(p - d)\,t f_t$.

Resistance to tearing between inner row of rivets, and shearing outer row of rivets $= (P - 2d)\,t f_t + (^1/_4\,\pi d^2)\,f_s$.

Resistance to shearing three rivets $= 3\,(^1/_4\,\pi d^2)\,f_s$.

Resistance to crushing in front of three rivets $= 3\,t d f_c$.

Resistance to tearing at inner row of rivets and crushing in front of one rivet in outer row $= (P - 2d)\,t f_t + t d f_c$.

Strength of solid plate $= p t f_t$.

**Double-riveted Lap-joint with Inside Cover-plate,** Fig. 10.—Resistance to tearing at outer row of rivets $= (P - d)\,t f_t$.

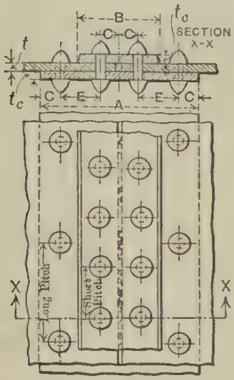

FIG. 11. Double-riveted Butt-joint

Resistance to shearing four rivets $= 4\,(^1/_4\,\pi d^2)\,f_s$.

Resistance to tearing at inner row and shearing outer row of rivets $= (P - 1\,^1/_2\,d)\,t f_t + (^1/_4\,\pi d^2) f_s$.

Resistance to crushing in front of four rivets $= 4\,t d f_c$.

Resistance to tearing at inner row of rivets, and crushing in front of one rivet $= (P - 1\,^1/_2\,d)\,t f_t + t d f_c$.

Strength of solid plate $= P t f_t$.

**Double-riveted Butt-joint,** Fig. 11.—Resistance to tearing at outer row of rivets $= (P - d)\,t f_t$.

Resistance to shearing two rivets in double shear and one in single shear $= 5\,(^1/_4\,\pi d^2)\,f_s$.

Resistance to tearing at inner row of rivets and shearing one of the outer row of rivets $= (P - 2d)\,t f_t + (^1/_4\,\pi d^2)\,f_s$.

Resistance to crushing in front of three rivets $= 3\,t d f_c$.

Crushing in front of two rivets and shearing one rivet $= 2\,t d f_c + (^1/_4\,\pi d^2)\,f_s$.

Strength of solid plate $= P t f_t$.

**Triple-riveted Butt-joint,** Fig. 12.—Resistance to tearing at outer row of rivets $= (P - d)\,t f_t$.

Resistance to shearing four rivets in double shear and one in single shear $= 9\,(^1/_4\,\pi d^2)\,f_s$.

Resistance to tearing at middle row of rivets and shearing one rivet $= (P - 2d)\,t f_t + (^1/_4\,\pi d^2)\,f_s$.

Resistance to crushing in front of four rivets and shearing one rivet $= 4\,d t f_c + (^1/_4\,\pi d^2)\,f_s$.

Resistance to crushing in front of five rivets $= 5\,d t f_c$.

Strength of solid plate $= P t f_t$.

**Quadruple-riveted Butt-joint with Two Cover-plates,** Fig. 13.—Resistance to tearing at outer row of rivets $= (P - d)\,t f_t$.

Resistance to tearing at the third row and shearing one rivet in the outer row $= (P - 2d)\,t f_t + (^1/_4\,\pi d^2)\,f_s$.

Resistance to tearing at the second row of rivets and shearing three rivets $= (P - 4d)\,t f_t + 3\,(^1/_4\,\pi d^2)\,f_s$.

Resistance to double shearing eight rivets and single shearing three rivets $= 19\,(^1/_4\,\pi d^2)\,f_s$.

Resistance to crushing in front of eight rivets and single shearing three rivets $= 8\,d t f_c + 3\,(^1/_4\,\pi d^2)\,f_s$.

Resistance to crushing in front of eleven rivets $= 11\,d t f_c$.

Resistance to tearing at the third row of rivets and crushing in front of one rivet in the outer row $= (P - 2d)\,t f_t + d t f_c$.

Resistance to tearing at the second row of rivets and crushing in front of three rivets $= (P - 4d)\,t f_t + 3\,d t f_c$.

Strength of the solid plate $= P t f_t$.

**Table 2.—Dimensions and Efficiency of Double-riveted Butt-joints.** (See Fig. 11)

All joints fail by tearing the plate between rivet holes in the outer row.

| Thickness of Plate, in. | Thickness of Straps, in. | Diam. of Holes, in. | Efficiency, percent | Long Pitch, in. | Short Pitch, in. | *A*, in. | *B*, in. | *C*, in. | *D*, in. |

**Lap-riveted Girth Joints.**—(Boiler Book of Hartford Steam Boiler Inspection & Insurance Co.)—In horizontal tubular boilers, tanks, and similar vessels, it is customary to use the same size of rivets in both girth and longitudinal seams. If the heads are not stayed by tubes or through braces, the strength of the girth joints should be at least 50% of that required for the longitudinal joints. The joints in Table 5 are designed to meet these requirements; a higher efficiency could be obtained in some cases by using a different size of rivet. It is assumed in each case that the efficiency of the corresponding longitudinal joint is not greater than that of the standard design of quadruple-riveted butt-joints given in Table 4.

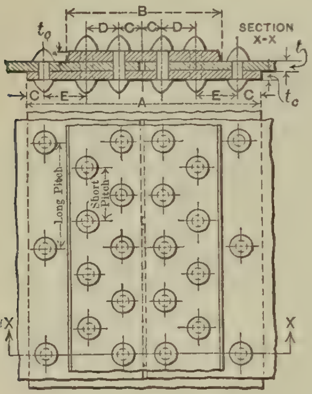

Fig. 12. Triple-riveted Butt-joint

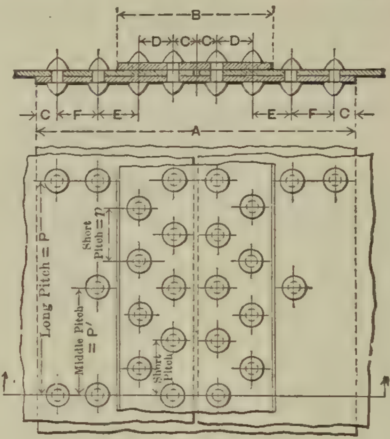

Fig. 13. Quadruple-riveted Butt-joint

**Table 3.—Dimensions and Efficiency of Triple-riveted Butt-joints.** (See Fig. 12)

Joints for plate thicknesses of 3/4 in., and 7/8 in. to 1 in. (both inclusive), fail by tearing the plate between rivet holes in the second row and shearing a rivet in the outer row. All other joints fail by tearing the plate between rivet holes in the outer row.

| Thickness of Plate, in. | Thickness of Straps, in. | Diam. of Holes, in. | Efficiency, per-cent | Long Pitch, in. | Short Pitch, in. | *A*, in. | *B*, in. | *C*, in. | *D*, in. | *E*, in. |

| 15/16 | 11/16 | 1 5/16 | 83.7 | 9 | 4 1/2 | 20 1/4 | 13 1/4 | 2 | 2 5/8 | 3 1/2 |
| 1 | 3/4 | 1 7/16 | 83.4 | 9 1/2 | 4 3/4 | 22 | 14 1/2 | 2 3/16 | 2 7/8 | 3 3/4 |

Where 50% of more of the load which would act on an unstayed head of the same diameter as the shell is relieved by the effect of tubes or through stays, as in tubular boilers, the strength of the girth joints should be at least 35% of that required in longitudinal joints. When the girth joints are exposed to products of combustion, the shearing strength of the rivets should be not less than 50% of the full strength of the plate corresponding to the thickness at the joint. Table 6 is designed for such conditions, using rivets of the same size as standard butt-joints. Plates thicker than 9/16 in. are not advised if the girth seams are exposed to fire or products of combustion. In those portions of the seams exposed to fire, the riveting should be started at the bottom of the boiler and carried up continuously on both sides, reaming the holes anew as the riveting is carried up to the full diameter of the boiler.

**Precautions to be Observed in Making Riveted Joints.**—Plates must be brought into close contact before the rivet is driven, either by bolts close to the rivet hole, firmly drawn up, or by a power-actuated holding device. The latter sometimes is incorporated in power-driven riveting machines.

**Table 4.—Dimensions and Efficiency of Quadruple-riveted Butt-joints.** (See Fig. 13)

Joints for 3/4 in. and 7/8 in. to 1 1/4 in. plates (both inclusive) fail by tearing the plate between rivet holes in the third row and shearing the rivets in the two outer rows. All other joints fail by tearing the plate between rivet holes in the outer row.

Rivet holes must be perfectly aligned in the members that are to be joined. This is best insured by drilling of the members. Punched holes, usually used in structural work, are difficult of alignment, and have a stress set up around the hole which seriously impairs the strength of the plate unless it is subsequently relieved by reaming, drilling, or annealing. Punched plates or structural members in which the holes do not align never should be brought into alignment by drifting with taper pins. This practice usually causes serious injury to the plates or structural members. The best practice with punched members is to punch the holes smaller than required, and after assembly, ream or drill them to the correct size.

The rivet must completely fill the hole, and consequently must be upset throughout its entire length. Otherwise, an undue concentrated stress, either in bearing or in shearing, may be brought upon adjoining rivets. To insure complete upsetting all of the larger sizes of rivets should be power-driven. Care must be taken in machine riveting to avoid applying a riveting pressure that will set up stresses in the plate tending to crush it. It is essential in machine riveting that the pressure be so applied that the heads are concentric. Pressure should be maintained on the rivet until it has cooled sufficiently to hold the plate firmly.

## FASTENINGS FOR TIMBER JOINTS

**METHODS OF FAILURE.**—Wooden framed structures, especially roof trusses, towers, bridges and trestles tend to fail at bolted joints. Fig. 1 shows the method of failure when the wood is stronger than the bolt. In Fig. 2, where the bolt is the stronger, the joint fails by deforming and splitting the wood. Drawing the bolt up tight creates friction between the surfaces and retards slipping. Shrinkage of the wood decreases the friction and promotes failure.

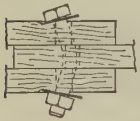

FIG. 1. Wood Stronger than Bolt

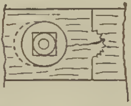

FIG. 2. Bolt Stronger than Wood

Methods of Failure of Wood Joints

**METHODS OF FASTENING WOOD JOINTS.**—Fig. 3 shows various fastenings for wood joints. At *A* is the simplest bolted joint, with a washer under the head and nut, which is adequate in well-dried timber, when there is little tension, or a large number of bolts. If the washer is made with prongs, as at *B*, tendency to slip is much reduced. The insertion of a washer of substantial thickness in counterbored holes on mating faces of the joint, as at *C*, prevents slipping, up to the point where the pressure on the end wood tends to crush the fiber. If the faces of the washer are serrated, as at *D*, the tendency to slip is further minimized.

The steel plate, with prongs at right angles, inserted between the members of the joint, as shown at *E*, covers practically the entire area of contact and makes a firm non-slipping joint. A variation of this construction is shown at *F*, in which ribbed cast-iron plates are substituted for the steel plates with prongs. A ring washer, as shown at *G*, adds largely to the strength of the joint, since it affords external resistance to slipping on the outside of the ring, as does the plain washer, but also adds internal resistance on the portion of the wood within the ring. Rings of this type should be tapered into the wood to obtain full bearing surface. A similar construction is shown at *H*, except that the washers are made of hard wood. They should be placed with the grain of wood in the washer parallel to the grain of the wood in the timber.

# MECHANICAL SPRINGS

By Mortimer F. Sayre

## 1. TYPES OF SPRINGS

**DEFINITIONS.**—A mechanical spring is a resilient machine member used for the absorption or redistribution of energy. Springs are made in many forms to meet a variety of conditions. The more usual types are:

**Helical Springs. Compression, Extension, or Torsion.**—A helical spring comprises a bar or wire coiled in the general form of a helix, the bar advancing like the thread of a screw.

**Cone, Double Cone, and Keg Springs.**—A cone spring is one form of helical spring, but is wound on a tapered mandrel. A double cone spring may be considered as two similar cone springs joined at the small ends. A keg spring may be considered as two similar cone springs joined at the large ends. These types usually are compression springs.

**Volute Springs** are conical springs made from a flat bar, which is so wound that each coil partially overlaps the next adjacent coil.

**Leaf or Laminated Springs** are made of flat or slightly curved bars, plates, or *leaves*, of regularly varying lengths, superposed on each other.

**Elliptical Springs; Semi-elliptical and Full Elliptical** are the commonest of the leaf springs. The latter may consist of one or more parallel units, designated as *Single Full Elliptic*, *Double Elliptic*, *Triple Elliptic*, etc. A semi-elliptic spring, or one unit of a full elliptic, comprises a number of plates of rectangular section, superposed on each other. The term elliptical spring is sometimes extended to include all forms of leaf springs.

**Spiral, Clock, or Power Springs** lie in one plane, and are wound around a fixed center, continually receding from it.

**Special Flat Springs** usually are made of a single metal strip or bar, initially flat, formed into any one of a great variety of shapes.

**Disc Springs. Ring Springs.**—The disc or " Belleville " spring comprises a series of dished or otherwise specially shaped discs, which act similarly to spring washers, in combined bending and direct stress. The ring spring is composed of a series of metal rings of alternately larger and smaller diameter, which bear against each other along wedge-shaped or conical faces. As the spring is loaded in compression, the individual units are driven together and stressed in tension or compression.

**SPRING MATERIAL.**—Table 1 covers the principal materials used for springs. The compositions given are typical, and can be modified somewhat to meet special requirements.

For hot-coiled helical compression springs, of material $^1/_2$-in. round or larger, for railroad car and locomotive suspensions and for general industrial purposes, Grade 5 or a similar steel with 0.15% minimum Si content requirement is used almost universally. Alloy steels have not proven very satisfactory. The same material generally is used for hot-wound helical extension and torsion springs, cone and keg springs, and volute springs.

Small helical and special shape coiled springs of $^3/_8$-in. round, or smaller wire, usually are wound cold from Grades 8 or 10. Grade 7 is used occasionally for severe service requirements.

For automobile valve springs (small helical compression) Grade 6 in electrically melted and cold-drawn steel has been successful. Special precautions are required throughout all fabricating processes, to eliminate surface defects in the finished wire. Straight carbon steel of Grade 8 may be used as an alternative.

Safety-valve and pop-valve springs usually are made from Grade 5. For marine work, to minimize atmospheric corrosion, they often are nickel plated.

Cone shaped upholstery springs are made of Grade 10.

For elliptic springs in railroad car and locomotive suspensions Grade 5 is popular, but Grade 6, and some special alloys, have found favor, particularly silico-manganese steel, S.A.E. 9250, S.A.E. 9260, or A.S.T.M. Specification A 59–27. Surface defects in the material used in elliptic springs are not apt to be serious; in helical springs they are fatal.

Elliptic springs for automobile suspensions are sometimes made of Grade 5, but more often of silico-manganese steel, S.A.E. 9250, S.A.E. 9260, or chrome-vanadium steel, S.A.E. 6150, or other special alloys.

* Sheet; wire approximately 20 to 25,000 lb. greater. † Sheet. ‡ 100 kg. § Quenched and tempered. ¶ Varies with reduction from last heat.

For special flat springs for brake beam hangers, agricultural seat springs, etc., Grade 5 or an alloy steel may be used.

Small flat springs for general purposes usually are made of Grade 4.

Music wire Grade 9 is recommended for small helical springs operating under severe conditions. It is the strongest, stiffest, toughest and most uniformly made wire on the market.

To resist corrosion, small sizes of helical springs have been made from stainless steel Grade 11. An increasing number of springs are being made from chrome-nickel-steel (18% Cr, 8% Ni) Grade 12. Other metals used are brass, phosphor-bronze, German silver, Monel metal, and alloy steels. Brass and phosphor-bronze are recommended for springs which must resist moisture; phosphor-bronze is tougher than brass and resists fatigue better. Springs of these materials must be larger than steel springs for the same

### Notes for Table 1

Note 1. 1. WSS = Watch spring steel. 2. CSS = Clock spring steel. 3. MSS = Motor spring steel. 4. FSS = Flat spring steel. 5. HRB = Hot rolled bars. 6. CV = Chrome-vanadium steel. 7. AHC = Annealed high-carbon wire. 8. OTW = Oil tempered wire. 9. MW = Music wire. 10. HDS = Hard-drawn spring wire. 11. CW = Straight chromium wire and flat strips; corrosion resistant. 12. 18–8 = Stainless steel wire and flat strip; corrosion resistant. 13. LCN = low-chromium, 2% nickel strip; corrosion resistant. 14. 30C = 0.30–0.40% carbon wire and flat strip; heat resistant. 15. HB = High brass. 16. SB = Spring brass. 17. CB = Clock brass. 18. NS = Nickel-silver. 19, 20. PB = Phosphor bronze. 21. MM = Monel metal.

Note 2. Cleaned and annealed strip is cold rolled to correct size.
Note 3. Heat treated before forming.
Note 4. Heat treated before or after forming, depending on sharpness of required bends.
Note 5. Open hearth or electric steel, rolled in rod or bar mill.
Note 6. Electric steel rod, annealed.
Note 7. Cold-drawn to size.
Note 8. Heat treated after forming.
Note 9. Annealed after drawing.
Note 10. Quenched and tempered, usually after forming.
Note 11. If formed after hardening, is blued to remove strains.
Note 12. Highest grade electric steel.
Note 13. Basic open hearth steel.
Note 14. Cold-rolled or drawn from annealed bars or strips.
Note 15. 60% reduction to spring temper.
Note 16. 35% reduction to hard temper.
Note 17. Wire reduced 70% to spring temper.

Note 18. Varies with size: 0.177 in. = 210,000 lb.; 0.054 in. = 260,000 lb.; 0.020 = 300,000 lb. Elastic Limit: 0.177 in. = 75% of ultimate strength; 0.020 in. = 85% of ultimate strength.

Note 19. Varies with size: Ultimate strength, 0.187 in. = 230,000 lb.; 0.062 in. = 300,000 lb.; 0.032 in. = 350,000 lb.; 0.015 in. = 400,000 lb. Elastic limit = 60% of ultimate strength.

Note 20. 60% of ultimate strength.

Note 21. Cold-rolled or drawn to various degrees of spring hardness; does not possess the higher elastic limits of hardened and tempered carbon steels.

Note 22. Wire, 3 to 8%; sheet, 1 to 2%.
Note 23. Mainsprings for watches.
Note 24. Clock springs; brush holder springs.
Note 25. Phonograph and motor springs; used where forming properties are important.
Note 26. Locks; clips; spring washers; flat springs generally.
Note 27. Heavy coil or flat springs; formed hot and heat treated.
Note 28. Used for special applications.
Note 29. Scale springs; highest grade wire springs, especially in coarse sizes.
Note 30. Spiral springs generally.
Note 31. High grade, small and tough springs.
Note 32. These springs have high shock resistance, but will take a small set if overloaded.
Note 33. Flat and helical springs generally to resist corrosion.
Note 34. Stiff, resilient flat springs.
Note 35. Springs to resist stress under heat. Must be polished after tempering to resist corrosion.
Note 36. Flat or coiled springs for electrical equipment and for moderate stress.
Note 37. Flat springs with sharp bends or threaded holes.
Note 38. Better class springs, and where white color is desired.
Note 39. To resist corrosion at normal temperatures.
Note 40. Stiff resilient springs, corrosion resistant.
Note 41. To resist corrosion at high temperatures (except sulphurous gases).

Note 42. Varies as size.

| | | | | | |
|---|---|---|---|---|---|
| Diam., in. = | 0.187 | .125 | .062 | .032 | .015 |
| Ult. Str. = | 140,000 | 150,000 | 175,000 | 190,000 | 200,000 |

Note 43. Varies as size.

| | | | | | |
|---|---|---|---|---|---|
| Diam., in. = | 0.187 | .125 | .062 | .032 | .015 |
| Ult. Str. = | 180,000 | 200,000 | 225,000 | 250,000 | 265,000 |

duty. This is due to the lower unit stress necessary for such materials, and also because both brass and bronze are approximately 10% heavier than steel of the same dimensions. Monel metal is useful for springs subjected to heat and moisture.

For springs to resist corrosion and fatigue, beryllium copper has been strongly recommended. This alloy of copper contains usually 2 to 2.25% beryllium, is very susceptible to heat treatment, and after heat treatment develops a tensile strength of 150,000 to 175,000 lb. per sq. in. The Johnson's elastic limit is stated to be from 75,000 to 130,000 lb. per sq. in., depending on amount of cold work and on heat treatment. Young's modulus of elasticity is 16–18,000,000. Beryllium copper increases in strength and decreases in ductility very rapidly on cold working. The resistance to fatigue in the form of springs is stated to be unusually high for a non-ferrous metal, being comparable to that of spring steel.

## 2. HELICAL COMPRESSION AND EXTENSION SPRINGS

**DESIGN FORMULAS.** **Notation.**— $d$ = diameter of (round) bar; $D$ = outside diameter of spring; $k$ = ratio $D/d$; $H$ = free length of spring; $h$ = solid length of spring; $I$ = inactive portion of length, due to flattened ends, or to loops; $n$ = number of active helical turns or coils; $P$ = compressive or extensile load on spring; $C$ = maximum allowable load; $S$ = maximum fiber stress in the section, ignoring direct shear and effect of curvature; $S'$ = true maximum fiber stress; $f$ = extension or compression of one coil with load $P$; $f_n$ = extension or compression of $n$ coils with load $P$; $G$ = torsional modulus of elasticity. All dimensions in inches; all loads in pounds.

The stress usually is assumed to be pure torsion. The standard formulas for round section are:

$$P = \frac{S\pi d^3}{8(D-d)} = 0.3927\,\frac{Sd^3}{D-d} \quad . \quad . \quad [1]; \quad f = \frac{8P(D-d)^3}{G d^4} = \frac{S\pi}{G}\cdot\frac{(D-d)^2}{d} \quad . \quad . \quad [2]$$

If $S$ be the maximum permissible stress, $f$ in the last formula is the maximum permissible deflection per coil. The deflection in the whole spring may be obtained by multiplying $f$ by the number of effective coils in the spring. In helical compression springs (see Fig. 1) it is customary practice to design the springs with sufficient space between coils so that they can be closed solid in the manufacturer's test, and return to the desired free height. Then $f$ becomes the allowable space between coils, and $C$ is the capacity or load required to close the spring solid. The free height is

$$H = n(d + f) + I \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [3]$$

The solid height is

$$h = nd + I \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [4]$$

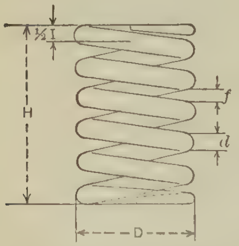

FIG. 1. Helical Compression Spring

In fabricating hot-rolled helical compression springs, the ends of the bars are tapered before coiling, so that the finished spring will have flat ends. Sometimes the ends are ground after coiling, so that the ends will be truly square with the helical axis; this is regular practice with valve springs. The inactive length added to the spring by the two tapered ends is about $I$ = 1.25 $d$ for ordinary flat ends, and somewhat less for ground ends.

**CORRECTION FOR CURVATURE (THE RÖVER CORRECTION).**—The stress in a spring due to direct shear, while neglected in the above standard formulas, often is considerable. The formulas also neglect the curvature of the bar. These errors have been examined mathematically by A. Röver, and his conclusions verified experimentally by A. M. Wahl, with very satisfactory accuracy. The correction (for the two errors combined) is as follows: If $D/d = k$, and the true maximum stress = $S'$, then:

$$\frac{S'}{S} = \frac{4k-5}{4k-8} + \frac{0.615}{k-1} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [5]$$

| For $k$ = | 3.5 | 4.0 | 4.5 | 5.0 | 6.0 | 7.0 | 8.0 | 10.0 | 12.0 | 16.0 |
|---|---|---|---|---|---|---|---|---|---|---|
| $S'/S$ = | 1.746 | 1.580 | 1.476 | 1.404 | 1.311 | 1.253 | 1.213 | 1.162 | 1.131 | 1.095 |

This true maximum stress $S'$ is present at only a single point element in the section, the point on the surface of the bar at the extreme inside of the helix. Care must be exercised in using a localized stress such as this as the sole criterion of design. With hot-rolled springs, or other springs with moderately roughened surface, it is probable that stress concentration due to curvature will be masked, in part, by the effects of other stress concentrations due to irregularities of surface. The values of $S'/S$ given above then exaggerate the true effect. For music wire springs, or springs with smooth wire surface, carefully made so that other stress concentrations are absent, it is probable that the

Röver curvature correction should be used almost, if not quite, in full. This is particularly true if fatigue is an important factor. Engineers are not in agreement on these points and further experimental work is needed.

Note particularly however that if the Röver curvature correction factor is to be used in design, the allowable working stresses must be changed to correspond. This is necessary if the two formulas are to give concordant results over that range of values of $k$ within which the old standard formula has been satisfactory. Taking $k = 8.0$ as a mid-point in that range, the corresponding value of $S'/S$ is 1.213. If a stress of 100,000 lb. per sq. in. has given good results with a given material and the standard formula, then for the same material, using a formula containing the Röver correction, a design working stress of 121,300 lb. per sq. in. should be used, and pro rata for other stresses.

**TABLES FOR HELICAL SPRING DESIGN.**—Table 2 is taken from A.S.T.M. Tentative Specifications for Heat-Treated Carbon Steel Helical Springs (A125–33). It represents maximum test loads for typical railroad type springs. The Röver curvature correction is not included. A torsional modulus of 10,500,000 was used to compute deflections. When using this table to find total deflection, the deflection per coil should be multiplied by the number of completely free coils in the spring, treating one coil at each end, measured from tip of tapered bar, as inactive.

Table 3, based partially on data prepared for the Wallace Barnes Co., gives for smaller sizes of springs, three items: 1. Load in lb. at 100,000 lb. per sq. in. fiber stress, Röver curvature correction ignored. 2. Load in lb. at 100,000 lb. per sq. in. fiber stress, computed on basis of Röver curvature correction formula. 3. Deflection in inches per coil per 1000 lb. of load, computed for a modulus of elasticity of 11,500,000.

In these two tables, working loads and the corresponding deflections for other unit stress than 100,000 lb. per sq. in. may be obtained by changing the tabular values in the corresponding ratio of stresses. For other moduli of elasticity than those used for the tables, vary the deflection in inverse ratio to the modulus.

EXAMPLES.—1. Find safe load and deflection for a steel spring of 15 effective coils, 0.50 in. outside diam., made of 16 gage wire (0.0625 in. diam.). *Solution.* From Table 3, safe load $w_1$ at 100,000 lb. fiber stress for this spring is 21.9 lb., ignoring curvature correction, or 18.1 lb. corrected for curvature. Deflection is 0.00382 in. per lb. per coil; total deflection $= 0.00382 \times 15 \times 18.1 = 1.037$ in. under full load.

2. Design a spring to carry a load of 50 lb. with a deflection of 2.5 in. Use fiber stress of 120,000 lb., including correction for curvature. *Solution.* A load $w_2$ of 50 lb. for 120,000 lb. fiber stress is equivalent, by proportion, to a load of 41.7 lb. under 100,000 lb. fiber stress. The following choices are possible among others:

| | Wire diam., in. | Coil diam., in. | $w_2$ | $f$ | No. of coils |
|---|---|---|---|---|---|
| 1. | 0.080 | 0.4375 | 41.5 | 0.000776 | 64.5 |
| 2. | 0.0915 | 0.625 | 44.7 | 0.001507 | 33.2 |
| 3. | 0.1055 | 1.000 | 43.7 | 0.00402 | 12.5 |

The desired deflection per lb. for this spring is 2.50/50, or 0.05 in. The required number of effective coils is $0.05/f$ in each case.

3. Design a phosphor-bronze spring to carry a load of 50 lb. with deflection 2.50 in., using maximum stress of 50,000 lb. and torsional modulus of 6,000,000. *Solution.* A load of 50 lb. with a unit stress of 50,000 lb. is equivalent to 100 lb. load under 100,000 lb. stress. The following choices are possible among others:

| | Wire diam., in. | Coil diam., in. | $w_2$ | $f$ | No. of coils |
|---|---|---|---|---|---|
| 1. | 0.1205 | 0.500 | 117.0 | 0.000180 | 144 |
| 2. | 0.125 | 0.625 | 109.4 | 0.000356 | 77.8 |
| 3. | 0.135 | 0.875 | 102.0 | 0.000848 | 34.9 |
| 4. | 0.148 | 1.000 | 118.0 | 0.000897 | 29.1 |

The desired deflection per pound is 2.5/50, or 0.05 in. Since phosphor-bronze with a modulus of 6,000,000 is to be used instead of steel with a modulus of 11,500,000, the deflection per pound will be greater than those given in the table in the ratio 11.5/6, and the number of coils will equal $(0.05 \times 6)/(11.5 \times f)$.

**MODULUS OF ELASTICITY.**—The normal value of the torsional modulus of carbon steel ranges from 11,000,000 to 12,000,000, averaging 11,500,000. The actual value to be used in design, however, varies with three factors.

1. The modulus decreases with increasing temperature at the rate of approximately 0.015% per deg. F. change, this rate of change increasing at higher temperature. Except for precision instruments or for high temperature work, this change usually can be neglected.

2. By initially overloading a spring, the metal in the spring may be cold-worked, and the apparent elastic limit of the spring raised, so that higher allowable stresses may be used in design. The effect of this overstressing is to lower the torsional modulus of the spring under future loading. In heavily overstressed springs, the torsional modulus may be reduced by as much as 5 to 15%.

**Table 2.—Test Loads and Deflections for Heat-treated Helical Carbon Steel Springs**

Corresponding to a maximum fiber stress of 100,000 lb. per sq. in. (A.S.T.M. Specification A125–33)
*L* = Test load, lb.; *D* = Deflection, in. per turn, for *G* = 500,000 lb. per sq. in.

3. In compression helical springs with flattened ends, a certain amount of twisting occurs in the metal of the so-called inactive coils, as well as in the completely free coils. The true equivalent number of coils in the spring is equal to the number of completely free coils, plus one-quarter coil for each flattened end. It has been customary to compute total deflection by multiplying deflection per coil by the number of completely free coils, ignoring deflection in the flattened ends. When this was done, the error was tacitly corrected in design by using a somewhat lowered value of torsional modulus, so that for springs of usual length, correct numerical results were obtained. This accounts for the low torsional modulus values of 10,500,000 to 11,000,000 often used in practical design.

For most extension springs a similar end effect is present. In springs with the commonly used hook ends, formed by bending up the last half coil, each hook is equivalent to 0.1 coil added effective length.

**HOT-COILED HELICAL COMPRESSION SPRINGS.**—The permissible design stress varies somewhat with the service required. For Grade 5 spring steel, in as-formed condition (commonly used for heavy railroad springs), ignoring the Röver correction, 80,000 to 95,000 lb. per sq. in. may be used. By coiling the springs to an initial height much greater than the final free height desired and then compressing the springs beyond their yield point, entrapped stresses may be introduced and the apparent maximum fiber stress appreciably increased, up to 110,000 to 115,000. At these limiting figures the life of a spring in any service, except a practically steady load, would be very short. Provided the maximum normal load in service is well below the peak capacity, and the travel or range of movement is not too great or too frequently applied, a design stress of 90,000 lb. per sq. in. based on peak capacity usually is safe.

For smaller sizes of helical springs (wire 3/8 in. diam. or smaller) used in compression, stresses of 100,000 or sometimes as high as 120,000 lb. per sq. in. may be used, if impact stresses or fatigue conditions are not severe. It is customary to reduce these allowable stresses by 20% for springs used in extension. Further reductions must be made if the springs must withstand large numbers of repetitions of loading.

**HOT-COILED HELICAL EXTENSION SPRINGS.**—The fundamental formulas are the same as for compression springs. Design stresses, however, should be lower. A maximum stress of not over 60,000 lb. per sq. in. for large springs under service conditions is recommended. Even at this stress the spring will usually take a small amount of permanent set when tested. In figuring overall length under load, allowance must be made for this set. Alternatively, the spring may be designed so that at the desired unloaded length, there will be a space between coils of 40% to 50% of the desired elongation per coil. This gives leeway for the manufacturer to coil the spring close, and then apply such test loads that when unloaded it will have the desired free length. By so doing, the apparent elastic limit is raised, and the spring should take no further permanent set under maximum stresses up to 60,000 lb. per sq. in.

**COLD-COILED HELICAL COMPRESSION SPRINGS.**—Several different grades of steel wire are in common use. Permissible design stresses vary not only with the grade, but also with the size of wire, and type of service. When not subject to severe impact or

*Continued on p.* 10–12.

**Table 3.—Safe Loads and Deflections for Smaller Sizes of Helical Extension and Compression Springs**

$w_1$ = load, lb., for fiber stress of 100,000 lb. per sq. in., curvature correction neglected.
$w_2$ = load, lb., for fiber stress of 100,000 lb. per sq. in., curvature correction considered.
$f$ = deflection, in. per 1000 coils, per lb. of load.

fatigue, a maximum stress of 90,000 lb. per sq. in., when the spring is solid, is safe for all grades and sizes. With the smaller sizes of wire, 100,000 lb. per sq. in. may be used. In cases of severe impact or fatigue, stresses should be reduced to 80,000, or even 60,000 lb. per sq. in. These figures are for use with the customary design formula, which ignores correction for curvature. In case the Röver curvature correction factor is used, the allowable stresses just given may be increased by 20%. For special service, or materials, higher stresses may be used, but a reputable manufacturer then should be consulted.

Stresses for good quality brass wire may be taken at 40% of the above figures; for phosphor-bronze wire at 50%. Torsional modulus with steel may be taken at 11,000,000 to 11,500,000, if the design stress is conservative. For high stresses it will be lower.

Cold-coiled springs are coiled in multiple lengths, the ends are dressed, either automatically or by hand, and are then ground square, or have their end coils bent down flat. An allowance of 1.25 *d* should be made for the inactive height.

**COLD-COILED HELICAL EXTENSION SPRINGS** usually are coiled with initial tension, produced by partly overlapping the wire as it is fed into the coiling machine. A very considerable load must be applied before the initial tension is neutralized and the spring begins to elongate. The fundamental load formula is applicable, but, owing to the initial tension, extensions cannot be accurately predicted. Springs can be made without initial tension, and the same conditions then apply as for hot-wound extension springs.

Stresses for cold-coiled helical extension springs of steel wire, not subject to severe impact or fatigue, usually are limited to 80,000 lb. per sq. in. (96,000 to 100,000 lb. per sq. in. with Röver correction).

The ends of extension springs are commonly formed into hooks, loops, or some other shape, to permit the extensile load to be applied to the spring. See Fig. 2.

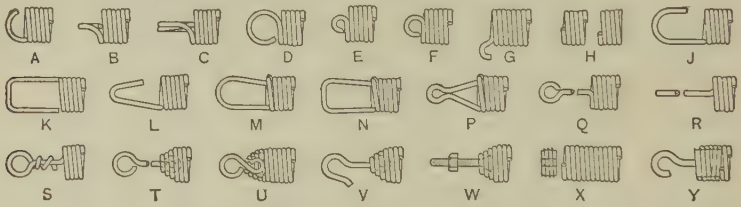

FIG. 2. Types of Spring Ends. *A*, Hook over center. *B*, Loop over center. *C*, Loop of two coils over center. *D*, Loop of one coil on side. *E*, Small eye on side. *F*, Small eye over center. *G*, Small hook on side. *H*, Plain ends—one end ground. *J*, Long hook. *K*, Square long loop. *L*, V-shaped hook. *M*, Knotted loop. *N*, Square knotted loop. *P*, Knotted eye. *Q*, Extended eye from center. *R*, Straight end from center; part of straight end usually annealed so that it can be twisted to attach to other parts or to form an eye, as shown in *S*. *T*, Extended swivel eye in tapered end spring; commonly employed when the ends must be safeguarded against breakage. *U*, Regular swivel eye in tapered end spring. *V*, Special-shaped swivel hook in tapered end spring. *W*, Swivel threaded bolt in tapered end spring. *X*, Plain end to screw on threaded plugs. *Y*, Plain end attached to special threaded plug.

**DOUBLE COIL SPRINGS,** consisting of two concentric helical compression springs, one inside the other, often are used. Triple coils, consisting of three concentric springs, also are common. A double coil spring, for a given design stress, is more flexible than a single coil of the same capacity and outside dimensions. Usually the concentric coils are of the same free height; but by making one of the springs (usually the inner) shorter than the other, a graduated effect, *i.e.*, a change in slope of the load-deflection curve, is produced. In double coils of common railroad sizes the clearance between the outer and inner springs should be $1/16$ in. all around. Thus in a spring 6 $1/4$ in. outside diameter, with an outer coil of 1 $1/4$-in. round bar, the inner coil should be 3 $5/8$ in. outside diameter. In very large or long springs, the clearance should be $3/32$ or $1/8$ in.

In a double coil spring properly designed there is a definite relation between the bar sizes of the outer and inner coils. If the design stress is the same for both coils, and if there is no inactive height, the index $D/d$ should be the same for both coils. Practically, since the inner coil always has the smaller bar diameter, its design stress can be somewhat greater, and its inactive height ($I = 1.25\,d$) somewhat less, than for the outer coil; hence its index can be a little the smaller of the two. Using commercial sizes of bars, this relation must be approximate in some cases, but should be adhered to as closely as possible.

**SQUARE WIRE.**—For helical compression or extension springs of square steel

$$P = \frac{0.4163\,Sb^3}{D - b} \quad \ldots\ldots\ldots\ldots [6]; \qquad f = \frac{5.57\,P(D - b)^3}{Gb^4} = \frac{2.32(D - b)^2 S}{Gb} \quad \ldots\ldots\ldots [7],$$

where $b$ = side of square bar, in.; $P$ = load corresponding to stress $S$; $D$ = outside diam. of spring, in.; $G$ = torsional modulus of elasticity; $f$ = deflection, in. per coil. If the Röver correction for curvature is to be included, the stress $S$ as given by these equations must be further multiplied by the curvature correction factor following formula [5].

When coiled into a spring a square bar upsets into a keystone section, with the larger side next to the coiling mandrel. The amount of this upset is difficult to predict, but a roughly approximate formula is: Upset = $0.3\,b^2/(D - 2b)$. See Fig. 3. Allowance must be made for this upset in figuring the solid height of the spring. Its effect upon stiffness and strength is relatively small, except in springs of very small spring index. Bars initially rolled to a keystone section sometimes are used, with the smaller side placed next to the coiling mandrel. In this way, after coiling, a square section is obtained.

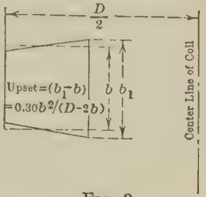

FIG. 3

For the same working stress, the safe load with square wire is 6% greater than with round wire of diameter equal to the side of the square. The deflection per pound of load is 70% as great; the deflection for a given unit stress is 74% as great for the square as for the round wire.

**RECTANGULAR SECTIONS.**—Helical compression or extension springs made of rectangular bars are not very common, but sometimes they will meet requirements that no round bar spring can fulfill. The torsional theory of rectangular bars is quite complex. The fundamental formulas for springs are:

$$P = \frac{\alpha a b^2 S}{R}. \quad . \quad . \quad [8]; \quad f = \frac{2\,\pi P R^3}{\gamma G a b^3}. \quad . \quad . \quad [9]$$

where $R$ = mean coil radius measured from center of coil to center of wire; $a$ = in all cases, the longer side, and $b$ = the shorter side of the rectangular bar, irrespective of whether the spring is made up with the bar coiled edgewise or flatwise; $f$ = deflection per coil; $\alpha$ and $\gamma$ are constants (see Table 4); $G$ = torsional modulus of elasticity.

Similar formulas for bars of elliptical section are as follows:

$$P = \frac{0.1963\, a b^2 S}{R}. \quad . \quad . \quad [10]; \quad f = \frac{2\,\pi P R^3}{\beta G a b^3}. \quad . \quad . \quad [11].$$

Values of $\beta$ are given in Table 4.

Table 4.—Values of Constants for Torsion in Rectangular and Elliptical Bars

| $a/b$ = | 1 | 1.25 | 1.5 | 1.75 | 2 | 2.5 | 3 | 4 | 10 | Infinite |
|---|---|---|---|---|---|---|---|---|---|---|
| $\alpha$ = | 0.208 | 0.221 | 0.231 | 0.239 | 0.246 | 0.258 | 0.267 | 0.282 | 0.312 | 0.333 |
| $\gamma$ = | .141 | .172 | .196 | .214 | .229 | .249 | .263 | .281 | .312 | .333 |
| $\beta$ = | .0982 | .1197 | .136 | .147 | .157 | .169 | .177 | .185 | .194 | .196 |

In many cases flattened wire, made by passing round wire through rolls, is used rather than truly rectangular wire. In these cases the moduli $\alpha$ and $\gamma$ may be multiplied by 0.85 to 0.95, depending on how nearly the shape approximates a true rectangle.

In rectangular sections, as in square, the upset of the bar in coiling must be considered in design. The allowable design stress in rectangular bar springs is greater than in rounds, and increases as the ratio $a/b$ increases. For large ratios it may be as high as 125,000 lb. per sq. in. This is because the stress is maximum at only two points in the section, *viz.*, the middle points of the long sides.

Correction for curvature in springs of rectangular or elliptical section is complicated by this same fact that maximum stress, as given by the above formulas, exists only at the middle point of the long sides, while the maximum stress increase due to curvature occurs at the midpoint of the side parallel to and nearest the axis. If the wire is coiled with the long side parallel to the axis, the stress must be multiplied by the same curvature correction factor as for round wire springs. See p. 10–06. If the bar is coiled with the long side perpendicular to the axis of the coil, the point of maximum stress in torsion comes at a point on the bar at which the curvature correction factor is unity, and if the bar is appreciably out of square the curvature correction factor can be neglected.

**CONICAL HELICAL SPRINGS.**—Conical springs have the following advantages: 1. By making the difference in diameter of successive coils equal to or slightly greater than the thickness of the wire, the coils may be made so to nest together as to give, for a given total extension, a small solid height as compared to that for cylindrical springs. 2. If made with uniform initial pitch between coils, the outside coils will bottom before the inner coils; the spring will show an increasing stiffness with load, rather than a constant stiffness. This curved load-deflection line may be desirable in special cases. 3. Conical springs have somewhat greater lateral stability than cylindrical springs. On the other hand, in conical springs as usually designed, much of the metal is only partially stressed; to carry a given load with a given deflection, from 50% to 100% more metal may be needed than in a cylindrical spring.

Volute springs, hot coiled from flat bar stock, are used to some extent in railroad work in Europe. They are not used in the U. S.

**The Safe Load on a Conical or Volute Spring** is the same as that on a cylindrical helical spring made of the same size wire or bar, and of a diameter equal to the maximum diameter of the cone. The stiffness depends on the number of coils in action at any one time, and on the minimum and maximum coil diameters. Deflection per pound of load at any instant $= (f/P) = (16\,n/Gd^4)\{(R_2^2 + R_1^2)(R_2 + R_1)\}$, where $R_1$, $R_2$ = respectively, minimum and maximum radii, measured from center of coil to center of wire; $n$ = number of coils; $d$ = wire diameter; $G$ = torsional modulus of elasticity.

## 3. TORSION SPRINGS

**HELICAL TORSION SPRINGS** act to transmit a twist instead of a direct pull. This twisting action may be used to: 1. Maintain a steady torque to hold an object in place, with only enough motion to compensate for wear or readjustment. 2. Store up energy while the spring is being coiled, and to restore the energy when the spring is uncoiled. 3. Absorb shocks when power is applied to rotate a shaft, or to act simply as a buffer.

**DESIGN FORMULAS.**—The stiffness of the spring, in terms of torque required to produce a given angle of twist, depends only on the material and the size of wire used, and on the length of wire. Number of coils, and within reasonable limits, the spacing between coils, have no effect except as they may determine the length of the wire.

Similarly, the maximum safe load in inch-pounds of torque that may be applied to the spring depends only on the size and material of the wire used. The length of coil has no influence. The radius of the coil is important only in that, if the spring is too sharply coiled, a minor correction must be applied to provide for the effect on strength of this too-sharp curvature.

For springs of round wire, the formulas used are as follows:

Torque or turning moment developed, in.-lb., is

$$M = \pi d^3 S/32\,k = d^3 S/10\,k \qquad [13];$$

$$\omega = \frac{1167\,ML}{E\,d^4} = \frac{114.6\,SL}{E\,d\,k} \qquad [14];$$

$$L = \frac{E\,d^4\,\omega}{1167\,M} \qquad [15].$$

For rectangular wire, these formulas become:

$$M = \frac{S\,b\,d^2}{6\,k} \qquad [16];$$

$$\omega = \frac{687.6\,ML}{E\,b\,d^3} = \frac{114.6\,SL}{E\,d\,k} \qquad [17];$$

$$L = \frac{E\,b\,d^3\,\omega}{687.6\,M} \qquad [18].$$

In these formulas, $b$ = breadth of rectangular wire, parallel to axis of coil; $d$ = diam. of wire, or thickness of rectangular wire, perpendicular to axis of coil; $L$ = effective length of wire in coiled portion of spring, plus a small allowance for length of wire in projection lugs; $\omega$ = angle turned through, deg.; $S$ = unit stress in wire; $E$ = modulus of elasticity in bending of spring material = 30,000,000 for steel; = 15,000,000 for phosphor-bronze or brass; $k$ = correction factor for effect of sharp curvature. See Table 5 for values of $k$ for different values of spring index, *i.e.*, ratio of mean diameter of coil to diameter of wire.

It has been general practice to omit the curvature correction factor $k$ from these formulas, tacitly caring for it by using a value of allowable stress which has been determined experimentally to work satisfactorily for springs of average spring index. An objection to this method is that an unnecessarily large amount of metal will be used for springs of large index, while springs of small index will be overstressed and may fail. More economical

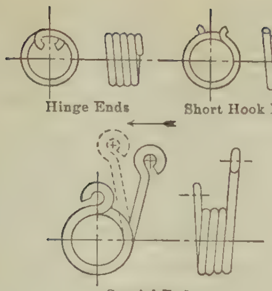

Fig. 4

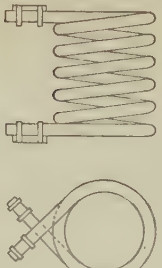

Fig. 5

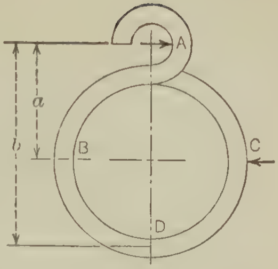

Fig. 6

results may be obtained by using an allowable stress value 8 to 10% larger, but inserting the proper curvature factor in the formulas.

Examples.—1. Design a helical torsion spring for a screen door, 30 in. wide, to develop a pull at the handle of 1 lb. with the door just opened, and of 3 lb. after the door has been turned through 180°. Use round wire with allowable unit stress of 150,000 lb. per sq. in. *Solution.*—Maximum turning moment developed = $3 \times 30 = 90$ in.-lb. From equation [13], $d^3/k = (10 \times 90)/150{,}000 = 0.006$. Assuming a spring index of 6, $k = 1.142$. Substituting and solving, $d = 0.218$. For a spring index of 6, outside diameter of coil will be $(6 + 1) \times 0.218 = 1.52$ in. From equation [15], $L = (30{,}000{,}000 \times 0.218^4 \times 180)/(1167 \times 90) = 116.1$ in. This length is equivalent to 28.4 coils of 1.30 in. mean diam.

2. Design a helical torsion spring of square wire for a window shade to develop a maximum pull of 3 lb. on the shade after 15 revolutions. Diameter of roller = 1.25 in. *Solution.*—Maximum turning moment developed = $3 \times 0.5 \times 1.25 = 1.875$ in.-lb. In this case, in the equation for rectangular wire, $b = d$ and $d^3/k = 6M/S = (6 \times 1.875)/150{,}000 = 0.000075$. As a first trial, let $k = 1$; then $d = 0.042$ in. Assuming the mean diameter of the spring inside the shade roller to be 0.625 in., the approximate value of the spring index will be $0.625/0.042 = 14.9$. From Table 5, the corresponding value of $k = 1.046$. Resubstituting $d^3 = 1.046 \times 0.000075$, $d = 0.0428$ in. $\omega = 15 \times 360 = 5400°$. $L = (30{,}000{,}000 \times 0.0428^4 \times 5400)/(687.6 \times 1.875) = 421.6$ in., equivalent to 215 coils, 0.625 in. mean diameter. Actually a slightly larger size wire, with correspondingly greater number of coils, might be used.

**DESIGN SUGGESTIONS.**—The following comments, from *The Mainspring* (Wallace Barnes Co.), will aid in the design of helical torsion springs:

1. While the spring as a whole is acting in torsion, the wire itself is being bent, not twisted. For manufacturing reasons, it may be cheaper and more expedient to make the spring of round wire. Inherently a square or a rectangular shape is better in bending than a round one; if space or weight limitations are important, square or rectangular wire often may be substituted to advantage. *a.* Flat wire, made by running round wire through flattening rolls, often is used instead of true rectangular wire. Due to its rounded corners, its stiffness and strength is 5 to 10% less than true rectangular wire, but it usually is easier to manufacture and handle. *b.* For a powerful torsion spring in small space, flat wire, coiled edgewise, may be advantageous.

2. The twisting action exerted by a torsion spring cannot be transmitted by means of a one-point contact, as the hook used with extension springs. A clamp or a firm two- or three-point contact is needed at each end of the spring. In simplest form, one of the necessary two points of contact may be furnished by a lug projecting inward or outward at the end of the coil, as in Fig. 4. A thimble placed within the coil and bearing against the inside of the wire at a point 90° away from the lug could furnish the other contact point. Alternatively, clamps may be used as in Fig. 5 to furnish these two points of contact at each end of the spring.

The shorter the lever arm between the lines of pressure through the points of contact, the greater the pressures must be to give the desired twisting moment. With stiff springs, lugs projecting outward rather than inward, will reduce the resulting bearing pressure exerted at the lug. If the end of the coil is supported externally rather than internally, the points of contact being at

**Table 5.—Curvature Correction Factors for Torsion Springs**

| Spring Index | Curvature Correction Factor $k$ | | Spring Index | Curvature Correction Factor $k$ | | Spring Index | Curvature Correction Factor $k$ | | Spring Index | Curvature Correction Factor $k$ | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | Rectangular Wire | Circular Wire | | Rectangular Wire | Circular Wire | | Rectangular Wire | Circular Wire | | Rectangular Wire | Circular Wire |
| 3 | 1.286 | 1.332 | 6 | 1.124 | 1.142 | 10 | 1.072 | 1.080 | 16 | 1.043 | 1.049 |
| 4 | 1.200 | 1.229 | 7 | 1.105 | 1.119 | 12 | 1.057 | 1.066 | 20 | 1.036 | 1.039 |
| 5 | 1.153 | 1.175 | 8 | 1.091 | 1.103 | 14 | 1.049 | 1.056 | 40 | 1.017 | 1.019 |

*A* and *C*, Fig. 6, with 270° of coil between them, the useful torque is determined by the lever arm *a*; the stress in the wire at the point of contact is controlled by the greater lever arm *b*. The wire along the major portion of the length of the spring is no more heavily stressed when the external support is used than with the internal thimble; but with the external support, the stress at the one danger point is greater than the average stress in the ratio $b/a$. The useful load on the spring then must be reduced proportionately. This difficulty can be avoided by using an internal thimble, or by using clamps as in Fig. 5.

3. Always so place torsion springs that they will coil up under load. All cold-coiled helical springs have internal stresses as a result of the methods used in forming the spring. These stresses act to form a hidden safety factor, strengthening the spring against failure under a repetition of the same kind of deformation as originally caused the stresses but weakening it under stresses in the opposite direction. In general, if material in springs, or other types of construction, is to be heavily stressed in a direction opposite to that in which it was stressed in forming, the material should be heat-treated after shaping.

4. Long torsion springs, like long compression springs, but unlike extension springs, tend to be unstable laterally and to buckle on moderate provocation. This can be counteracted: *a*. By care in clamping or so holding the spring at the ends as to provide a slight degree of lateral support, and avoiding skew pressures that would tend to start buckling. Less desirable alternatives are: *b*. Providing a slight degree of lateral support along the length of the spring. *c*. Placing the spring under a small initial tension, tending to hold it straight.

5. As a torsion spring is loaded, its coil radius changes. Inside and outside clearances must be provided to permit these changes in radius. For example, a spring, 10 coils long, whose maximum twist is to be 0.5 revolution, will change by 0.5/10, or 5% in radius of coil. That much clearance, at least, must be present.

6. The longitudinal spacing between coils also changes. In the case just cited, initial spacing should be at least 5% of the wire diameter. A slight excess will prevent rubbing action. Unless frictional resistance is definitely desired, close-coiled springs should not be used.

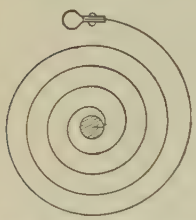

Fig. 7. Spiral or Power Spring

7. For best results, the spring should act in torsion only, with the center line of the coil coinciding with the axis of rotation. Sometimes clearance conditions prevent this, and the spring must be placed off-side. If this is done the spring will bend laterally as well as twist in operation. Successful results may be obtained under these conditions, but care is required, and lower stresses must be used.

**SPIRAL OR POWER SPRINGS,** Fig. 7, usually are made of thin cold-rolled strip steel. Under ideal conditions, the strip acts as a long curved beam subjected to a uniform bending moment throughout its entire length. The fundamental formulas are the same as for helical torsion springs of rectangular steel. The maximum torque exerted by the spring upon the central shaft is equal to the bending moment in the strip considered as a beam, and

$$M = S\,b\,h^2/6. \qquad [19]$$

Working stresses in this formula may run extremely high, 150,000 to 200,000, or even 250,000 lb. per sq. in. The higher values should be chosen only after consultation with a spring manufacturer. Rigorously, the curvature correction factor *k* should be introduced in this formula as in the equivalent formula for helical torsion springs. Practically, the radius of curvature is usually so large, compared to the thickness of the strip, that the correction can be neglected. The angle of twist $\theta$ in radians is given by the equation

$$\theta = ML/EI = 12\,ML/E\,b\,h^3. \qquad [20]$$

Dividing by $2\pi$, gives $\theta$ in terms of revolutions of the shaft. See notation on p. 10-14.

Practically, these formulas must be used with caution. It is somewhat difficult to so support the springs as to produce pure bending in the ends, rather than a combination of bending and tension. The presence of tension or shear in the metal at the ends of the spring causes a variable, rather than a constant, bending moment throughout the length of the spring. The metal then is overstressed in some places and understressed in others.

The relation between bending moment and angle of twist is even more influenced by practical conditions. If the spring shaft is turned through more than moderate angles the spring begins to coil solid on the arbor, and *L*, the working length of spring strip, gradually decreases. Also, strips in successive coils begin to touch, and the resulting friction materially affects the torque acting on the shaft. Fortunately, where power springs are to store energy, the demand usually is for the maintenance of a certain minimum torque over the maximum angle of rotation. With the spring fully wound up, available torque is much greater than the desired minimum value, and the large amount of friction then present is not particularly detrimental. When the spring is nearly run down, and torque has dropped almost to the minimum allowable value, the coils no longer touch and friction is much smaller. Friction may be reduced by lubricating the sides of the strip.

In spiral springs used in precision instruments, or for hair springs in watches or clocks, the problem is entirely different. Here the angle of twist is relatively small compared to the length of the spring. The coils are so supported that at no time do they come in contact.

Cold-rolled strip steel, properly heat treated, is capable of extremely high fiber stresses. In making spiral springs it is usual to cut off the proper length of strip, slot or form the ends as required, coil the strip, and apply it in the assembly without previous forming, except as the coiling itself serves to form the shape. Until the elastic limit is exceeded, the stress developed during forming may be computed from

$$S = Eh/2R \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [21]$$

the strip being assumed to be changed from an initial straight condition to a radius of curvature $R$. If the strip has an initial radius curvature $R_1$, and is further bent to a radius $R_2$, the resulting change in stress is given by

$$S = \{(1/R_2) - (1/R_1)\}(Eh/2) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [22]$$

Usually the arbor about which the strip is coiled is so small that the elastic limit is exceeded, and the strip is given a permanent radius of curvature. This introduces internal stresses which act to strengthen the material under further bending applied in the same direction as in forming, but to materially weaken it if bent in the reverse direction.

## 4. ELLIPTIC AND SEMI-ELLIPTIC SPRINGS

**NOTATION.**—$L$ = length, in., of spring between hanger or bolt centers, under working load; $n$ = number of plates in spring; $b$ = width of plates, in.; $h$ = thickness of plates, in.; $B$ = width of band, in.; $P$ = working load, lb. applied at center of spring; $S$ = maximum fiber stress in plates, at load $P$, lb. per sq. in.; $f$ = deflection, in., of spring under load $P$; $E$ = Young's modulus of elasticity.

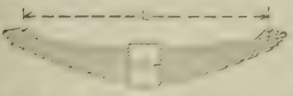

FIG. 8. Semi-elliptic Locomotive Spring

In the ideal case, the laminated semi-elliptic spring is considered as equivalent to a single flat plate supported at both ends and loaded in the middle, of uniform thickness $h$, and of width equal to $nb$ at the center and tapering regularly to zero at each end. The fundamental equations for this ideal case are:

$$P = 2Sbh^2n/\{3(L-B)\} \quad . . . [23]; \qquad f = 3PL^3/8Ebh^3n = SL^2/\{4E(L-B)h\} \quad . . . [24].$$

The case is supposed to be one of pure bending, direct shear being neglected.

In practice, a proportion of the plates are of length $L$ or longer. Hence the equivalent width of the single plate is not zero at the ends. This does not affect the load formula, but the deflection formula becomes

$$f = SKL^2/\{4E(L-B)h\}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [25]$$

$$K = \{(1-r)(1-3r) - 2r^2 \log_e r\}/(1-r)^3, \quad . \quad . \quad . \quad . \quad . \quad [26]$$

where $r$ = (number of plates of length $L$)/(Total number of plates.) Values of $K$ are given in Table 6.

Table 6.—Values of $K$

| $r =$ | 0 | 0.05 | 0.10 | 0.15 | 0.20 | 0.25 | 0.30 | 0.40 | 0.50 |
|---|---|---|---|---|---|---|---|---|---|
| $K =$ | 1.000 | .950 | .927 | .901 | .876 | .855 | .836 | .804 | .776 |

Deflection formulas for elliptic springs are at best only approximate. It is customary for manufacturers to make up a trial spring before executing an order.

**For Automobile Springs,** former practice was to design for a static deflection, of 2 to 2 1/2 in., front axle, and 6 in. rear axle, the car containing no passengers. The present trend (1937) is toward a static deflection, both axles, of 6 in. unloaded, 7 1/2 to 9 in. loaded, with a maximum possible deflection of 12 in. This gives a car with approximately the same natural frequency, 80 to 85 cycles per min. for both front and rear springs. To obtain the higher flexibility for front springs, it has been necessary either to increase materially the size of the front leaf spring or springs, or (usually) to use helical springs for the front wheels. Design stresses run 65–85,000 lb. per sq. in., unloaded and 150,000 lb. per sq. in. maximum for leaf springs.

**For Semi-elliptic Locomotive Springs** the maximum fiber stress under working load (weight on spring with locomotive stationary on level track) is standard at 70,000 lb. per sq. in., on the assumption that the spring has adequate reserve movement. This requirement, under average working conditions, will be met if the length of spring and thickness of plates are related as shown in Table 7.

Table 7.—Length and Thickness of Semi-elliptic Locomotive Springs

| | | | | | |
|---|---|---|---|---|---|
| Length of spring, in. | 22–27 | 27–33 | 33–40 | 40–48 | 48–57 |
| Thickness, in., ideal | 1/4 | 5/16 | 3/8 | 7/16 | 1/2 |
| Thickness, in., good practice | 1/4–5/16 | 9/32–3/8 | 5/16–7/16 | 3/8–1/2 | 7/16–9/16 |

**FULL ELLIPTIC SPRINGS** usually are so designed that they can be tested band to band. This insures against excessive deflection in service. For usual railroad service, if the maximum stress when springs are so tested does not exceed 125,000 lb. per sq. in., safe maximum stress at working load usually can be 80,000 to 85,000 lb. per sq. in. These stresses are for Grade 5 carbon steel (see Table 1). Alloy steel springs usually can be designed to somewhat higher stresses. Young's modulus of elasticity can be taken at 29,000,000 for all common grades of spring steel.

Fig. 9. Quadruple Elliptic Passenger Car Spring

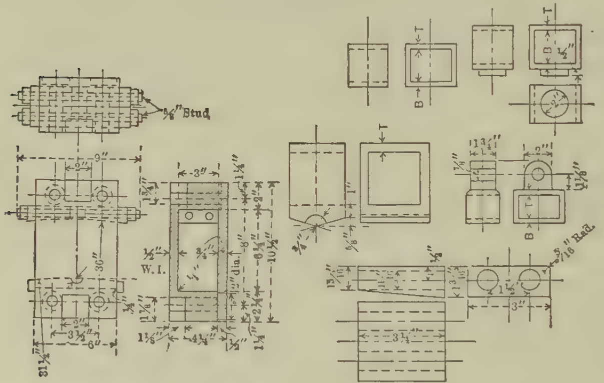

Fig. 10. Typical Bands

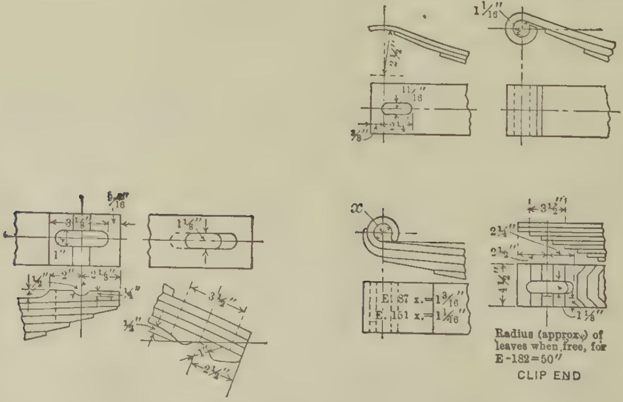

Fig. 11. Typical Elliptical Spring Ends

Fig. 8 shows a typical semi-elliptic locomotive spring. Fig. 9 is a typical quadruple-elliptic passenger car spring. In American practice all railroad elliptic springs are

" banded," or encircled with a cast steel or welded wrought iron strap. The latter has been most generally used, but cast steel bands are becoming more common. Fig. 10 shows typical styles of bands. For semi-elliptics the size of iron is usually from 3 × $^1/_2$ in. to 5 × $^3/_4$ in., depending on the size of spring. The " head " or side of the band running across the short plate, usually is heavier than the other three sides. It often bears a groove, a round dowel, a boss, or a hole, to position the spring on its seat.

The spring plates are " nibbed " at their centers, as shown in Fig. 9. This locks them together and into the band. The nib on the short plate is forced into the hot iron when the band is forged into place. Ends of the main plate on semi-elliptic springs are slotted, grooved, lipped, or turned into eyes, to provide engagement with the spring hangers. Fig. 11 shows typical ends, formed by welding steel pads on the ends of the main plate, or by attaching malleable iron end clips.

The bands of full elliptic railway springs usually are of 3 × $^3/_8$-in. iron on all four sides; sometimes a little heavier. Ends are either of eye-and-wrapper type, standard on passenger car elliptics, or are lipped to fit into end castings. The latter are known as the sectional type, and are standard for tender springs.

## 5. FLAT SPRINGS

**FLAT SPRINGS** is a term used to cover springs of a wide range of shapes, which are alike only in that they have all been made from originally flat strips. Simple flat springs are included, but the term also includes springs which have been twisted or notched out, bent or dished, each to meet special uses. Due to the wide range of shapes it is difficult to give exact design equations but the following statement of general principles taken from *The Mainspring* (Wallace Barnes Co) will be useful.

1. For highest efficiency, proportion each part of the spring to the load it must carry, no stronger and no weaker. Excess metal in the flexible part of a spring not only is useless in itself; it is undesirable, as it reduces flexibility, and so may result in a reduced, rather than an increased, safety factor. A tapering cantilever section is much more efficient than a plain rectangular strip.

2. As far as possible, place the metal so that it acts in bending rather than in torsion. A round rod is well adapted to resist twisting. Thin strip metal, no matter how dished or otherwise shaped, is weak and uneconomical under forces which tend to twist rather than bend it.

3. For parts of the spring where flexibility is desired, use a simple flat rectangular section. Added strength or stiffness, desired at any one point, can be obtained by crimping the metal longitudinally, but at a sacrifice in efficiency in absorbing energy.

4. Similarly, cupping the metal is an efficient method of obtaining local strength and stiffness at the expense of resilience.

5. Sharp bends are undesirable, both for manufacturing reasons and because of the serious localized stresses introduced in the material. A radius of curvature two or more times the thickness of the metal is advisable. Table 8 gives curvature stress factors.

**Table 8.—Curvature Stress Factor for Flat Springs**

$t$ = thickness of metal

| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| Inside Radius of Bend........ | 0.5$t$ | 0.75$t$ | 1.00$t$ | 1.25$t$ | 1.5$t$ | 2$t$ | 3$t$ | 4$t$ |
| Curvature Stress Factor...... | 1.523 | 1.370 | 1.286 | 1.236 | 1.200 | 1.153 | 1.105 | 1.060 |

6. For simpler cases of design, where a more or less straight rectangular strip can be used, the customary beam formulas for strength and deflection give satisfactory results. As deflection from a straight line becomes greater, or as bends are introduced (see Fig. 12-A) modifications become necessary. *a.* Correct values for strength can be obtained in all cases by using as $L$ in the beam formula the perpendicular distance from the point where stress is desired to the line of application

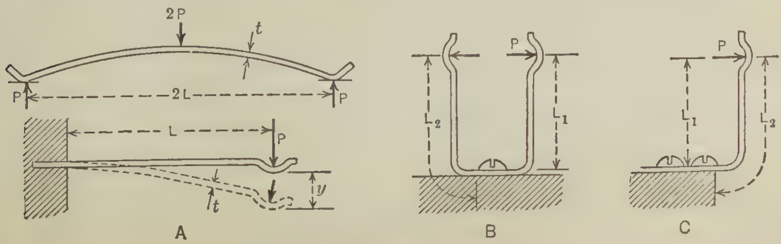

Fig. 12. Flat Springs

of the load. *b*. Correct values for flexibility can be approximated by using as $L$ a value intermediate between the length of the strip and this perpendicular distance, using judgment as to the exact value to use.

For a given maximum required spring deflection and given material, a definite relation exists between effective spring length and thickness of metal which gives the best results. If greater thickness of metal is used than this relation calls for, the metal will be overstressed and will fail. If a smaller thickness is used, the width of the spring must be increased by a far greater ratio than the thickness if reduced, in order to obtain sufficient stiffness. Where feasible, therefore, the best relation between spring length and thickness of metal should be approximated.

**DESIGN FORMULAS.**—The usual cantilever beam formulas may be used:

$$\text{Required section modulus} = b\,t^2/6 = PL/S \quad [27]$$

$$\text{Deflection} = PL^3/3\,EI = 2\,SL^2/3\,E\,t \quad [28]$$

where $b$ = width of spring; $t$ = thickness of spring; $L$ = effective cantilever length of spring; all in inches; $S$ = allowable stress = 150,000 lb. per sq. in. in good grade spring stock; $P$ = load on spring, lb.; $E$ = modulus of elasticity = 30,000,000 for steel; $I$ = moment of inertia. Using $S$ = 150,000 and $E$ = 30,000,000, equations [27] and [28] become
